COURSE OF LECTURES ON CLINICAL MEDICINE,

Delivered in the THEATRE of QUEEN'S COLLEGE, Birmingham

By SAMUEL WRIGHT, M.D.,

Physician to Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham; Physician to the General Dispensary; Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

Treatment of the dysentery of 1846; complications of it with dyspepsia; observations on the frequency of these; primary treatment of the dysentery; opium; cases in which large doses are needed; Dover's powder, effects of; stomach flatulence and intestinal flatulence, respective remedies for; hot bath; hip-bath; suggestions concerning them; opiate enemata, value of; secondary treatment of the dysentery; scybalous faeces, observations on the cause of; treatment of the cholera of 1846; value of opium; camphor in irritation of mucous membranes in old subjects; hydragryrum cum creta, value of; salines; stimulating baths; counter-irritation; mustard poultices; turpentine; cases in which the bowel-complaint superseded pre-existing diseases; diabetes; hooping-cough; skin diseases; scarlet fever; pyrosis; bromorrhoea; phthisis.

GENTLEMEN,—At the close of my last lecture I told you that the present one would consider the treatment of the dysentery and cholera of 1846, and of their sequelae.

The dysentery, as a rule, was not severe, but a few of the cases were very troublesome. As I mentioned, a few lectures ago, this ailment was generally complicated with dyspepsia. I am inclined to think that this usually happens with dysentery, not arising from ulceration of the intestines, or from other definite pathological causes. In the cases under notice, though the dejections were scanty, and chiefly composed of mucus and blood, and the straining severe, long continued, and frequent, yet there was no direct proof of ulceration of the bowels. Pressure made over the abdomen, at different points, was borne without complaining—it neither caused acute pain, nor sickness, nor increased tenesmus, as we generally find when ulceration exists. There are exceptions even to this rule, but they are so few as to weigh little against the practical value of its evidence. Moreover, there was not the excessive prostration which commonly accompanies ulceration; and, more than all, the ailment, in so far as I had an opportunity of seeing it, admitted of remedy, which is perhaps the best proof that its cause was neither serious nor deep-seated. Yet in some instances, as I have said, the morbid action was very severe, and productive of much suffering. In almost every case, however, the dysentery was preceded or accompanied by dyspeptic symptoms. Now, whether the former were a consequence or a coincidence of the latter, at least two forms of treatment were indicated. These were, first, to re-

lieve the immediate anxiety, pain, tormina, and tenesmus; and secondly, to improve the digestive function.

The most successful treatment consisted in giving, at once, an opiate proportioned to the urgency of the case. That you may understand what I mean by this, I must tell you that the physiological action of some medicines is considerably modified by the circumstances under which they are given. Opium is, perhaps, the most remarkable of this class. One grain of it, which is represented by twenty drops of laudanum, is a fair average dose for an adult; but there are occasions when an immense quantity of it can be borne, not only with impunity but without any obvious effect. In tetanus, for instance, this drug seems to be disarmed of its potency. Doses of it, that in ordinary cases would prove fatal, in this disease are of little or no effect. In severe pain, again, especially of the abdominal or pelvic viscera, a large opiate is generally required to produce good results. In the dysentery I allude to the symptoms, when not very urgent, were mostly mitigated by a dose of forty drops of tincture of opium; but, when very distressing, sixty drops barely served to alleviate them. I always preferred to give, for the first administration, the simple opiate diffused through a little warm water. My reason for not conjoining with it any other medicament was, that there was generally more or less gastric irritation, which prohibited other than narcotic or sedative remedies. This gastric irritation was seldom troublesome after the first full opiate; we were, consequently, left with the privilege of exhibiting other remedies, accordingly as they might be afterwards called for. Thus, the compound ipecacuanha powder, which the stomach would not have retained in the first instance, because of the nausea, was afterwards easily tolerated when that nausea had been subdued: in this manner, by a timely exhibition of the Dover's powder, we secured its valuable narcotico-audorific effects (the best possible in dysentery), without the annoyance of sickness or vomiting.

A distressing stomach flatulence was occasionally a prominent symptom. If attended with nausea, it was best not interfered with until after the first opiate had allayed this; and then, one or two drachms of compound spirit of ammonia, with laudanum, in hot water, relieved it like a charm. In other cases, intestinal flatulence was a conspicuous trouble. I found nothing to remedy this like equal parts (four or

five grains each) of compound soap pill and asafoetida. You will generally find that stomach flatulence is much benefited by ammonia, and little so by asafoetida; and that the converse applies to flatulence of the intestines.

An excellent adjunct to this opiate treatment was the hot bath. A complete bath was the most serviceable, because it determined more uniformly to the surface, and the better relieved internal congestion. The temperature I advised was from 100° to 108° Fah., in which the patient remained for five minutes, or longer, if he could conveniently bear it. Subsequently, he was well rubbed, from head to foot, with coarse towels. This is an important item in bathing, where you desire either to clear the skin or to promote free cuticular transpiration. Make it a rule never to advise a patient to take a bath without also advising him on this point.

When it was inconvenient or impracticable to obtain a full bath, I ordered the hip-bath, and found much good from it. Though it seldom relieved the abdominal pains effectually, it materially lessened the tenesmus, and in some cases dissipated it altogether. I employed it of the same temperature as above, and kept the patients in it from ten to fifteen minutes. You must be mindful, in using the hip-bath in dysentery, tenesmus, hemorrhoids, and such like affections, not to place your patient in a constrained position, or you will be likely to do more harm than good. Let him recline in such manner as to throw gravitation as little as possible towards the termination of the rectum.

In some cases in which an opiate given by the mouth did ineffectual service, it was excellently substituted in the form of enema. From forty to eighty drops of laudanum, according to the severity of the symptoms, I advised to be administered in a pint of gruel or starch. The latter is preferable, as being entirely free from irritating properties, and furnishing a convenient lubrication for the excited mucous membrane. This form of injection is sometimes invaluable in cases like those I am speaking of, as also in calculus vesicae, enlarged prostate, uterine disease, &c.: the opiate coming into immediate contact with the suffering part, or into close proximity with it, often affords much more immediate and even lasting relief, than is capable of being afforded in any other mode of administration.

To keep the patient in a recumbent position, and especially to keep his feet warm, was one of the most effective means of relieving the pains of

the dysentery that prevailed last year. These are excellent adjuncts to more direct treatment, and I advise you never to lose sight of them in intestinal disorders, whether acute or chronic.

After the relief of the more urgent symptoms of the dysentery, it became necessary to attend to the state of the stomach. Calumba, for reasons I have already given, was the most available tonic, in union with carbonate of soda and tincture of henbane, or hop: when much stomach flatulence prevailed, the soda was well substituted by compound spirit of ammonia, or its carbonate. So soon as ever the intestinal irritation permitted, a purgative of castor oil, or rhubarb and magnesia, was given, which generally brought away a considerable quantity of faeces, chiefly scybulous. Some of these were almost completely round, others oval: their discharge was constantly accompanied with flatus, often in profuse quantity. I mention this fact thus specifically, because you may hereafter meet with its repetition in practice, and be led to suspect serious mischief where really there is none. It is not uncommon for dyspeptics, who lead sedentary lives, to complain of constipation of the bowels, and of the hardened, rounded character of their faeces. To their own minds, the belief suggests itself that there must be a narrowing of some portion of the bowels, which first causes a retention of, and subsequently gives a configuration to, the matter of defecation. In all these cases, if no organic disease exist, you will find that the patients suffer considerably from intestinal flatulence. It is to this accumulated and retained air, exerting its pressure equally at all points, that the rotundity of the fecal matter is owing.

The treatment of the cholera of last year, of course, varied with the individuals who had the management of it. Practitioners, however, pretty generally agreed in the main of their remedies. Opium was of more value than any other single medicament. In full doses, repeated as often as necessary, it proved of excellent service. In many instances I found great use from camphor; this is often an admirable remedy in irritation of mucous membranes, especially of old people, as I have several times pointed out to you in treating cases of bronchial and vesical irritability, in such subjects, of late. I do not believe it to be so efficient in relieving irritation of mucous membranes in young people. Hyoseyamus, again, often did much good. Three grains of this, with three of camphor, and five of soap and opium pill, I was in the frequent habit of prescribing, and rarely without some good effect. When a mercurial was indicated, as on the occasion of the dejections being deficient in bile, *hydrargyrum cum creta* was the only one to be trusted. It seldom increased the purging, often relieved the sickness, and not often failed to promote the biliary secretion. In several cases, a scruple dose of the grey powder checked the vomiting at once, without at all increasing the action of the intestines. Calomel, in scruple doses, has been known to produce a like effect, but its sedative action under these circumstances is not always to be trusted; and, speaking from my own experience, I have so often seen it prove deceitful that I am little inclined to rely upon it when the bowels are in disorder.

In those cases of cholera in which the tongue was red, mouth hot, and epigastrium tender, ten-grain doses of carbonate of soda, as many drops of tincture of opium, and one or two drops of Scheele's aëti, in an ounce and a half of camphor mixture, was a very serviceable draught. In severe cases, its repetition every three or four hours generally did great good. When the tongue was pale and trembling, two drachms of compound spirit of ammonia well supplied the place of the soda.

The hot bath was an excellent adjunct to other treatment. In many instances I had reason to rejoice in its services. I always preferred the salt bath, made by adding three or four pounds of common salt to the water; or a more stimulating one, in which, in place of the

salt, two or three ounces of mustard were used. The object of this was more completely to excite the skin, and divert the deep-seated irritation. When a full bath could not be procured, the foot-bath was substituted: there being little tenesmus, generally, in the cholera cases, the hip-bath was not specially indicated.

Another form of treatment, which rarely failed to be of benefit, I must mention to you. This consisted of local applications to the epigastrium or abdomen. When simple warmth, with moisture, seemed only to be indicated, they were well furnished by large bran poultices. These are made by scalding a sufficiency of bran with boiling water, and, when properly cool, putting it in a calico or canvas bag, large enough to cover the entire of the abdomen. Heat and moisture are thus supplied easily, and are maintained without trouble or inconvenience for a long time. This poultice is much cheaper, cleaner, and more readily made, than one of linseed meal, and retains its temperature for a considerably longer period.

In urgent cases counter-irritation of an active kind was called for. When the gastric symptoms chiefly required to be counteracted, this was best done by the application of a mustard cataplasm, from six to eight inches square, over the epigastrium. These are most serviceable articles when you desire to produce an immediate action upon the skin. They act more quickly than a blister, and, though perhaps not so thoroughly, they have the greater advantage of seldom breaking the skin, and, therefore, of being capable of renewal almost as often as you may think fit. Some people advise, to add pungency to the mustard, that it should be mixed with vinegar. There is no need for this. A mustard poultice is never better made than when its fluid ingredient is warm water. It is of importance that the mustard should be recent: that which has been long kept, and especially if it have been exposed to air and sunlight, will prove of little value. When you desire to mitigate the acrimony of the mustard, as when about to apply a poultice of it to a very sensitive skin, or to a child's, this is done by adding to it one half, or the equivalent quantity, of flour or starch.

The mustard poultice applied over the epigastrium in the cholera cases I speak of was ordered to be retained there as long as the patient could conveniently bear it, which averaged between ten minutes and twenty. I never urged its protracted application, for fear of preventing a convenient repetition of it. This was made whenever circumstances required, and generally with good results.

When the irritation was more completely gastro-intestinal, a less potent counter-irritant than mustard was necessary. A mustard poultice of a few inches square is not a very formidable remedy; but one to cover the entire abdominal and gastric region is a very different affair. If you counter-irritate very actively an extensive surface, you may produce more mischief than at first you would suspect. It is possible, in thus injudiciously treating a patient, to occasion excessive irritability and exhaustion. I have known fatal sinking from a large abdominal blister. Instead of a mustard poultice, then, where we wanted to combat gastro-intestinal disturbance, turpentine was used. Like most volatile bodies, this cools any part to which it may be applied with freedom of evaporation; and, on the contrary, warms it when evaporation is prevented. A ready way of using it in this wise is to saturate with it a piece of thick calico, large enough to cover the part affected, to apply this calico uniformly to the surface; and then to cover the calico with oil-silk and a few folds of flannel. The turpentine, thus prevented from evaporating, is kept in close contact with the skin, which it stimulates sufficiently to produce heat, redness, and a tolerable degree of pain. An easy and elegant way of applying turpentine in these and other such cases is provided in the piline materials lately introduced to the profession by Mr. Markwick. These are of two kinds, called, from their relative thickness and

amount of coating, impermeable piline, and spongio-piline. To saturate either with turpentine, according as you want to produce more or less effect, and apply it to the part in question, is to save the longer and somewhat troublesome process I have just given.

This turpentine application to the bowels was of much use in the generality of cholera cases in which I tried it. It appeared to rouse the dormant energies of the system (a very natural effect of its absorption), and certainly mitigated the intestinal pain and discharge. In a few cases its absorption was attested by a violet odour of the urine; but in none did it produce the least stranguary, or other renal disorder. As the cholera symptoms declined, the remaining debility, gastric or other, was met most effectually in the mode I described when speaking of diarrhoea and dysentery.

I told you, gentlemen, in beginning this subject, that the bowel complaints of last year occasionally superseded others that had pre-existed. I had the opportunity of seeing many instances of this, and a few of them are curious enough to deserve mention.

I have already spoken to you of a dispensary patient of mine, whom some day I will introduce to you as a good example of diabetes permanently or temporarily arrested, time must tell us which. This man, William France, a workman in the manufactory of Mr. Bacchus of this town, was passing fourteen quarts of water every twenty-four hours, when he came under my care as a dispensary patient. Its specific gravity was 1010; it was very sweet, and gave other proofs, which on a future day I will detail, of containing a notable quantity of sugar. He continued stationary for nearly a fortnight, when he was suddenly seized with excessive purging. From the moment this commenced, there was a suspension of his diabetic symptoms: he passed not more than from two to four quarts of urine in twenty-four hours, and instead, as was his wont, of rising five or six times in the night to void it, never rose except to relieve his bowels: his urine acquired a deep colour, had a strong urinous smell, a salt taste, and contained not a trace of sugar: moreover, the excessive thirst and hunger decreased, and the skin perspired freely. This improved state lasted for five or six days, when the diarrhoea subsided, and the diabetic symptoms again made their appearance as urgently as ever.

Six months ago, I attended, with Mr. Bracey of this town, a little girl, two years and a half old, who was the subject of severe diarrhoea, or it might almost be called dysentery. This had suddenly supervened upon an attack of whooping-cough, and had completely supplanted it. The diarrhoea was treated with mild astringents, chalk, and small doses of opiate. These produced little effect, and we were about increasing their quantity, when the purging as suddenly ceased as it had begun, and the child's head became hot, and it screamed, and started in its sleep. On visiting it the next morning, we found it feverish and restless, with a very slight tendency of the eyes inwards. It was clear there was metastasis of the morbid action to the brain, or its membranes. He gave calomel to reproduce the purging, employed counter-irritation and other active remedies, but to no purpose: the child died of meningitis in sixteen hours after the unaccountable cessation of the diarrhoea.

In another case that occurred to my observation, a troublesome pustular eruption, chiefly affecting the face, back, and chest, that had lasted some months, and resisted every form of remedy, disappeared immediately on the occurrence of the bowel complaint (not antecedently to it), but returned, though in a mitigated form, as this subsided.

The little girl with the eruption round its mouth, which has lately been my out-patient at the hospital, was the subject of scarlet fever, the course of which was suddenly stopped by the occurrence of profuse diarrhoea. This was relieved by medicines, but the fever did not recur.

A rather striking case of pyrosis, of several

weeks' duration, was arrested directly on the supervention of dysentery, and did not return after this had subsided. A case of profuse bronchorrhoea was similarly checked; but, though the discharge did not recur after the cessation of the bowel complaint, the cough continued, and the breathing, before easy, became difficult. The case eventually improved. In more than one phthisical subject, I had occasion to notice a complete suspension of the night sweats, and of the expectoration, when the diarrhoea made its appearance. The exchange, however, was the reverse of salutary to the poor sufferers.

I find that our time will not permit me to enter further into these subjects; and for the same reason I must defer speaking of the sequelae of the bowel complaint, and their treatment, until our next meeting.

LECTURES ON INFLAMMATION.

By Dr. CORRIGAN.

Delivered at the Richmond Hospital School of Medicine, Dublin.

Lecture I.—INFLAMMATION.

GENTLEMEN,—I am sure it is not necessary on the present occasion to occupy your time with any introductory observations. You have already had the advantage of obtaining from my colleagues whatever information you might require in regard to your studies, and in relation to your efforts for success in your profession hereafter.

With regard to the importance of this particular branch of your studies it is hardly necessary to say a word; there is no one branch which is not of consequence to the student; but, without wishing for a moment to exalt any one above another—for all are essential to a subsequently successful career—still you are to recollect that the branch before us constitutes, if not the most, one at least of the most important, having for its object the cure of diseases; and, where that cannot be accomplished, the lessening of human suffering; to the attainment of which great ends all the other branches, however important in themselves, are subservient. Without further trespassing on your time, I shall proceed at the outset to draw your attention to a subject which appears to form a stumbling block to the student—I allude to inflammation.

This subject I shall take up only as far as it relates to the particular department before us—practice of medicine. I remember my own feelings, as a student, respecting this perplexing subject, and I am aware that it is not less puzzling to those commencing at this day; if, therefore, even at the risk of appearing tedious, I shall be able to remove some of the obscurity in which it is involved, I will consider myself sufficiently fortunate. If we take up some of the most accurate writers on the subject, for a definition of inflammation, we come to the end of the definition without any one distinct idea presented to our minds.

In making any definition the object ought to be the statement of some one fact, or sign, essential to the particular subject described, in order to prevent perplexity. Let us take up the article inflammation in almost any book, and see what are some of the difficulties attendant on this subject. We are told that in inflammation there are present, "heat of the part, tension, swelling, hardness, and for the most part a sensation of acute pain of a burning, heavy, pungent, or fixed character; that the colour is redder or darker than natural; the pulse most frequently full and hard, though often contracted; finally, that suppuration or gangrene ensues." But let us take any single one of these signs, and we don't find it an essential accompaniment of the lesion under consideration: for example, we find heat to exist only in particular instances; in others we have no means of determining whether it be present or not. Take common inflammation of the iris, we have no means by which to determine its absence or presence there. Tension is very often absent, swelling may be totally absent. In many acute inflammations, instead of hardening, the

part is often softer than natural; then we come to the nervous lesions—pain which is described as being so acute; but in how many instances is this symptom also absent? In some inflammations of the brain, pain is absent; there may be only the mere arrest of functions. These observations apply to each and every symptom ascribed to the presence of inflammation. In inflammations of serous membranes there is neither increased redness nor darkness of these structures; on the contrary, they may be lighter than natural. Again, you are told there is most often fever accompanying inflammation—a statement exceedingly dangerous to the beginner. For example, during the first twenty-four hours of acute pericarditis there is no fever, and so with other diseases; fever comes as the consequence of certain lesions, not as an early accompanying symptom. You see it as the consequence of a wound; not immediately after its infliction, but when inflammatory action has been set up. Thus you observe, as regards internal diseases, this would be a very bad characteristic to establish. Next, as to the pulse: in some of the most important diseases—pericarditis for example—the pulse, instead of being hard, full, bounding, &c., is exceedingly soft and small, requiring the exhibition of wine. Sometimes you will find the pulse natural, thus overturning all the rules laid down as diagnostic of inflammation.

We now pass to the nature and treatment of disease; and, go round the hospital, the same difficulty encompasses us. The pupil passes through the wards, he sees a case which is pointed out to him as pneumonia, and for which tartar emetic in large doses is given; yet, in the very next bed, a patient, also labouring under pneumonia, is taking mercury and opium. To what principles is the student to look for an explanation of these facts? He next sees a patient with inflammation of the mucous membrane of the large intestines, and to him opium is given in large doses; thus, again, he observes a departure from fixed principles. He next passes to the surgical wards, and there sees a case of inflammation of the conjunctiva treated by leeching, mercury, &c.; and the next moment a case of irritable ophthalmia, in which neither leeching nor mercury is used, but sedative applications and the internal exhibition of tonics; while to a third is applied nit. argenti, or some other caustic remedy. Again, amongst the host of skin diseases in the medical wards, the same confusion exists: so that an impression is absolutely forced upon the student's mind, that the whole treatment is the result of guesswork; he can conceive the existence of no guiding principle of treatment, for he sees remedies of an entirely opposite character administered in diseases of the same name, and included in the same class. Some late scientific writers, impressed with the enormousness of the term—inflammation, have proposed to discard it altogether; and among these is so high an authority as Sutherland; but we cannot, after all, proceed without it. Allison advocates the preservation of the term; and with him, Bennett, and others—these latter, however, stating that it should only be applied to those cases in which there occurs an exudation of the granules of the fibrine, as seen with the microscope in the liquor sanguinis. But let us come to test this proposition in practice, and we will find that a man may die of what can be called inflammation before this exudation has taken place; for instance a man may die of congestive pneumonia: the vessels throughout the whole lung are in a state of congestion, and in that state the patient dies; yet such a case must be excluded from the class of inflammations, if we are to view the term in the manner proposed.

With these difficulties surrounding us, what are we to do? In order to have any clear ideas of the term inflammation, we must strictly analyse it; to ascertain in what it consists, we must avoid connecting with it this effect or that, and endeavour to ascertain what particular morbid state we have to deal with, that we may be able to understand the rules which are to guide us

in the treatment. In the achievement of this great practical object, the discoveries of modern days furnish us with important aid. I allude to the results of microscopical observation, and these I shall take up as far only as relates to the particular subject under consideration.

In the elementary function of nutrition there exists in all living bodies a perfect similarity; the same system of nutrition that exists in the lowest vegetable exists equally in man; and to this the name of cytogenesis, or cellular nutrition, is given, from its being supposed that growth takes place by the development of cell after cell. But, without going into this question further, you are to remember that by nutrition is meant the process by which in all living bodies is effected growth—the formation of the new tissue that is required, and the removal of that which has done its office. This function exists before any trace of capillary circulation—before the formation of a single vessel can be discovered. Keeping this function by itself before our mind's eye, let us carry our analysis a little further. Before you is a diagram of the web of a frog's foot, as seen through the microscope; it will serve to illustrate our views; the capillary vessels are seen communicating in every possible way with one another, and may be considered as so many supply tubes carrying the materials to the cellular matrix, in which the process of cytogenesis, or cellular nutrition, is going on. There are here, then, two closely connected yet independent actions—circulation and nutrition.

It has been supposed—the opinion, however, being still a matter of theory, I merely mention it as serving to carry out an explanation—that the globules of fibrine found in the liquor sanguinis are the nucleated cells required for the purposes of nutrition, the vessels being the mere supply tubes. And this carries us to the second function, circulation, which, although intimately connected with that of nutrition, is yet independent, inasmuch that a lesion of the one may exist without necessarily involving the other. For instance, you can readily understand that the function of nutrition carried on in the interstices or meshes may not be in full vigour, that it may not draw from the blood globules in the usual amount, that its vigour may not be equal to that of the circulation; or, on the other hand, we can as easily suppose that the circulating vessels may become distended to double their usual size, carrying too great a quantity of blood globules: the function of mere nutrition may be comparatively unaffected.

Let us turn again, for a moment, to pathology, and we shall see two completely opposite pathological conditions classed under the same name—inflammation. Take peritonitis, what do we find here? We find an effusion of the fibrinous granules—in other words, the nucleated cells, and perhaps a proportion of serum constituting strictly a lesion of the nutritive function, but no disturbance, or little or none, of the capillary circulation of the part; there may be some vascular enlargement, but the lesion of the circulating function bears no proportion whatever to that of nutrition; the lesion of the nutritive function, in fact, here constitutes the leading character of the disease.

It, on the other hand, we pass to the extremities, or to the lungs themselves, we frequently find the part on examination darker or redder, or heavier than natural. Upon what does this depend? Not upon derangement of the nutritive function, not upon derangement of the granules of the fibrine, but the capillary vessels acquire two or three times their natural size, and at length become so distended that they have lost their tone; the circulation has ceased, the vessels have come at last to that point that all motion has ceased in them, the part dies—the lesion has ended in gangrene or death from a cessation of the circulation, and yet the function of nutrition has hardly been engaged; the patient has died before that function has become deranged. The same capillary distention is observed in bad cases of typhus fever, where the patient lies prostrate in the bed. Thus, you see, we are led

at once to the distinction of the cases to which I have been alluding as included under the one class—inflammation.

We will now advance a step further. In some of the lowest classes of animals we find hardly anything more than these two functions; but the higher classes possess something more than this elementary constitution. We find in them two classes of nerves—the one, the sympathetic system, or that of organic life; the other, that of animal life, or that which connects the living being with external objects, and endows him with sensation.

Mixed up with the two functional lesions already described as constituting severally pericarditis on the one hand, and congestive pneumonia on the other, he may have superadded a lesion either of that portion of the nervous system which connects the diseased part with the other portions of the body, or of the nerves of sensation giving rise to pain or disturbance of function. Thus, in proportion to the combined derangement of these three functions, we have what is called inflammation. If there be derangement of nutrition, we find exudation; if of circulation, redness or darkness of colour of the part, &c.; lastly, pain, if the function of innervation be involved.

Following out this system of analysis, you will see how it is that the definition of inflammation, as applied to any one organ of the body, cannot be applied to another. No definition can combine the symptoms or characters of this compound lesion as it occurs in the various organs of the body. You will also be able to understand on what depends the difference of treatment alluded to, or what seem to be conflicting principles in the mode of treating these diseases. Let us, by way of illustration, go back to the case of congestive pneumonia, which we spoke of, and ask ourselves what have we to contend with in that stage? We have to treat a derangement of the circulating function; the vessels are more distended than natural, the blood globules move slowly: there, as I told you, we use tartar emetic, with bloodletting, and if the patient be sinking we give stimulants. But turn to the patient lying in the next bed with the same disease, and you see him under mercurial treatment; and why? Because, as pathology shows us, after the vascular distention, the lesion of the circulating system has lasted some time, the nutritive function becomes implicated, and effusion of fibrine or of the nucleated cells takes place from the vessels into the cellular tissue of the lung, and thus there is superadded a lesion of the nutritive function, and sometimes not merely superadded, but taking the place of the deranged function of circulation, and becoming now the prominent lesion to be dealt with. Of all remedies we know that mercury has the most powerful influence over the derangement of the nutritive function, and in causing the absorption of those lymph granules; and for this reason we put the patient under mercury. Again we find that in some cases, or in somewhat similar cases, such as bronchitis, opium is added to the mercury; and why? For the purpose of allaying the irritation of the nerves of the part which sometimes exists.

In acute dysentery, see what occurs; mark the effect of leeching or bloodletting, as a means of relieving the lesion of circulation; of mercury, in correcting the derangement of the nutritive function; and the powerful effect of opium in checking the progress or preventing a recurrence the lesion of innervation.

These three functions, though separately affected, are most often in intimate connection, so that, though the nervous lesion may be a consequence of the derangement of the two first functions, we use the opium to remove it, for when it ceases to exist we break up the circle, while, if left alone, it might by the means of bringing back the lesions of the circulating and nutritive functions. This explains why it is that we use this remedy or the other in various proportions. Every case of inflammation, you are to remember, commences with one or other of

these three lesions, more or less marked, viz., the elementary functions of nutrition, of circulation, or that of the nervous system. Where the lesion of the nervous system is the greatest, as in neuralgia of the face, it shows itself as the primary lesion, commencing with acute pain, and followed by flushing of the cheek, swelling, and redness, with weeping of the eye. You there see, first, the lesion of innervation; second, that of circulation; lastly, deranged nutrition: the order of common inflammation being inverted in such a case. Here you would use—not such remedies as would lower the tone of the system, but first sedatives, to dull the increased sensibility; and, next, exhibit such internal remedies as would give a general tone to the constitution.

In acute rheumatism we observe opium given in very large doses, while we see an injury of a joint subjected to another and different mode of treatment. If we analyse a case of acute rheumatism, we find the observation of Sydenham perfectly borne out; he expressly states that it commences with pain, in other words, that the lesion of innervation precedes, by one, two, or three days, the lesion of the functions of circulation and nutrition; it is the first link in the chain of morbid actions, and hence we can employ opium in very large doses, and effectually, in its treatment, while we trust more to antiphlogistic remedies in common inflammation.

Still following up the same views, we can understand why occasionally we use a combination of opposite remedies, as opium, leeching, internal tonics, tartar emetic, bleeding, mercury, &c.

The adoption of this analysis throughout the long list of diseases that fall under the class inflammation will probably afford the student a clearer conception of the subject than he can obtain from the works that ordinarily come before him.

At our next meeting I shall take up more in detail the alterations of each particular function in itself

SUBSTANCE OF A LECTURE

By Sir B. BRODIE, Bart.

DISEASES OF THE SHOULDER-JOINT.

GENTLEMEN,—In my last lecture I entered upon the subject of counter-irritants, and I intended to pursue the subject to-day, but for particular reasons I postpone it for a time, and shall, on this occasion, speak of the diseases of the shoulder-joint. The shoulder-joint is not nearly so liable to disease as many other parts of the body, and this is probably owing to its proximity to the vital organs—the heart, brain, and spinal chord—also from its being protected by the great mass of muscle surrounding it: another cause may be named—it has not to support the weight of the body. But, though it is less liable to be affected than some other joints, yet the diseases which occur elsewhere may, and frequently do, also occur here; and should I enter into a history of diseases of this joint, and their treatment, I might well occupy several lectures; that, however, is not my intention. If you look into the remarks on diseases of the knee and hip joints, which I published some years ago, and which appeared in the journals of the day, you will find many of the most important observations on points which belong to those joints and the shoulder-joint in common; but I do not refer you to my own observations alone, but to information published by many others; and I propose to-day to speak chiefly of those morbid conditions which are peculiar to the shoulder-joint.

One of the most common diseases to which the shoulder joint is liable is inflammation of the synovial membrane. The circumstance of the large deltoid muscle covering it makes it less liable to this disease than the knee—resembling in this respect the hip-joint, which is protected by the gluteus muscle. Inflammation may occur in this joint as a local disease, as when a man has inflammation from a blow on the shoulder; but where it occurs once as a local disease, it takes

place as gout or rheumatism twenty times. Inflammation of the synovial membrane of the shoulder gives a sharp lacerating pain, more or less intense, according to the degree of inflammation, and this pain is referred to the joint itself. If the pain be in the immediate neighbourhood, the shoulder becomes swollen, and the swelling is sometimes much more considerable than you would imagine the capsular ligament would allow. But the shoulder-joint is never inflamed also, and the inflammation of these makes the swelling larger than if confined to the joint. The inflammation extending to these bursae produces also another symptom: when you handle the joint a sort of cracking sensation is produced as you touch it with the fingers; this sensation differs entirely from that produced by the grating of rough bones together, and will be readily recognised when once you have noticed it. It arises, I think, from the fluid in these inflamed bursae passing from one set of cells to another.

Inflammation of the synovial membrane of the shoulder-joint terminates in the effusion of serum, and also of coagulated lymph, but seldom of pus. Persons seldom die of inflammation of the synovial membrane of this joint, and opportunities of judging by examination after death are rare, more rare in cases of this joint than of any other. That lymph is effused into the interior of the joint, and also into the cellular texture external to it, is shown by the stiffness which always, more or less, according to the inflammation, follows this form of disease. Now, I said that this was very frequently an effect of gout, and therefore met with very much amongst the rich and idle. How will you be able to judge of this? There will be acidity of stomach, and weak digestion; you will find that the patient has been indulging in excess of eating, and drinking wine, has lived very much on animal food, and the urine will contain a large quantity of lithate of ammonia. This gouty attack of the shoulder may be distinguished from rheumatism by this, that the latter attacks several parts simultaneously; but gout, though it may move about from one part of the body to another, seldom attacks two places at once. After all, the distinction between gout and rheumatism is not very well marked, as shown by this circumstance, that we hear of rheumatic gout when the surgeon is doubtful to which it belongs. Inflammation of the synovial membrane of this joint, I suppose, may terminate in pus, in the joint, though I never saw that effect; it may also, perhaps, produce ulceration of the cartilage, though I am not certain whether I have seen it do so; but, at all events, it is more rare here than in the knee. If it did terminate in ulceration, then there would be more pain, and paralysis of the muscles of the extremity.

This disease is treated on the same general principles as inflammation of the synovial membrane of other joints. When it runs high, and there is much fever, you will take blood from the arm, or apply leeches, or cup the patient—not just on the joint, but in the neighbourhood, as the pressure of cupping will do it more harm than good. As in other cases, you administer purgatives, saline medicines, and diaphoretics, where the inflammation is acute. Having well purged the patient and given diaphoretics, you may give the vinum colchici in small doses of twenty drops three times a day; but never, on this or any other occasion, give colchicum till you have well purged the bowels; and I never give it without at the same time administering small doses of mercury: for its effect, we know, is to hinder the secretion of bile, as shown in the colour of the stools; and this is injurious, if carried to any extent. In cases of rheumatism, as is usual, give the patient calomel; he is often relieved by being mercurialized. In almost any case of inflammation of the synovial membrane of the shoulder-joint, as of the other joints, you may give mercury with advantage, so as to affect the gums just for a few days—it is not required long; and, besides these remedies, as the case is acute or chronic,

you may give guaiacum, pulvis ipsecacuanha comp., and sarsaparilla, as for the treatment of rheumatism elsewhere.

The next disease of the shoulder which I speak of has its origin in cancellous structure of the bone. You can cut it with a knife; it becomes very vascular, and filled with matter of a cheesy nature. Then you will recollect that this increased vascularity is followed by diminished vascularity, and this by ulceration of cartilage beginning on that surface which lies towards the bone; and where the articular cavity is perforated an abscess is formed which makes its way externally. This scrofulous disease of the shoulder-joint terminates differently from that of the synovial membrane; there is a small degree of pain in the first instance, and it never is very great till the abscess is making its way to the surface, and is aggravated by motion of the joint. When the abscess is formed it makes its way in one of two directions—either forwards or backwards; it cannot make its way through the deltoid muscle, for muscles seldom ulcerate, so it creeps along, either to the inferior or posterior edge. An abscess connected with scrofulous disease of the shoulder-joint presents a remarkable appearance—a globular tumour appearing to be enveloped in a serous cyst, just like an encysted tumour. I remember a case where a surgeon mistook an abscess of this kind for an encysted tumour, which it very much resembled, and proposed to have it removed, but the lady objected, and after a time it proved to be a scrofulous abscess. I remember a case in this hospital which shows how the disease takes this peculiar form:—A woman was admitted for a globular tumour near the shoulder joint, but she died of diseased lungs. I examined the body: there was scrofulous disease of the joint; the bone was soft, vascular, and cheese-like; an abscess was found in the interior of the joint, which made its way out by the course of the tendon of the biceps, and under the anterior edge of the deltoid muscle. You cannot fail to understand how it put on the peculiar form I have mentioned.

The treatment of scrofulous disease of the shoulder-joint is conducted in the same way as that of the knee-joint. I have sometimes put on a leather splint, formed to the shoulder, and, by straps, huckled to the opposite side of the chest; but this is not so necessary here as in scrofulous disease of the knee-joint, as it protects the knee from being rubbed against anything, and entirely prevents motion. This splint is of more advantage in protecting the shoulder from disturbance, than from limiting its motions. You may control its motion by fastening a bandage round the arm, and then passing it to the opposite side of the chest and tying it. With respect to the other part of the treatment, you attend first to the patient's general health; send him to the seaside, or let him live in the country air; let him have a generous diet, and have steel medicines, if they agree with him they are the best tonics; they must not be given unremittingly, but after a period of three weeks let the use of them be suspended for ten days, and then resume them for another similar period, stopping again for another ten days, and so on in like manner as before. The steel medicines must be taken for a long time, for they are intended to strengthen the constitution, and that cannot be attained at once; it will be necessary to extend their use over a period of three or four years, for it is not given so much with the intention of curing the disease, as of strengthening the constitution. Sometimes steel heats the patient, if given in the ordinary manner. You may then frequently make it agree with your patient by giving it thus:—let him have citrate of iron in an effervescing saline draught, or without effervescence; the iron gives tone to the system, and the saline tends to the skin and relieves the patient from any uncomfortable heat.

When iron cannot be made to agree, you may employ sarsaparilla or quinine, and other bitter tonics. But the best tonic, after all, is the sea-air; it is more useful than bathing; many go to the

seaside and imagine that it is the bathing which does them good—it is the air more than the bathing.

The cartilage of the shoulder-joint may ulcerate in consequence of this scrofulous disease of the synovial membrane; but one point I must remark—scrofulous disease of the shoulder-joint will generally get well, especially in young subjects, for the joint is of a simple construction, and for the same reason that fractures and various diseases of the upper extremity get well sooner than those of the lower, because of the greater proximity to the centre of the circulation. When it gets well, the patient may recover with more or less of a stiff joint; but ankylosis of the shoulder is less inconvenient than in many other joints, because the scapula is moveable on the trunk, and the increased motion of the scapula makes up in some degree for the diminished motion of the shoulder-joint.

If you have scrofulous disease of the knee which does not get well, you resort to amputation; can you do so as regards the shoulder? The disease is not confined to the joint alone, but extends to the scapula also. I never attempted it but once; a man came into the hospital with scrofulous disease of the shoulder, and after some time the disease appeared to be gaining on him, and the remedies employed did him no good; he seemed dying of disease of the shoulder, and I amputated the arm at the shoulder-joint. The head of the humerus was greatly diseased, and the disease extended down to the shaft of the bone, and the cartilage completely ulcerated; the articular surface of the scapula was deprived of cartilage, and was very soft; the abscess was found in the substance of the bone, just below the articular surface. Of course it was out of the question to heal the wound by the first intention, and the patient stayed a long time in the hospital, the wound healing by granulation, sometimes better and sometimes worse. All this time our endeavours were exerted for the improvement of his constitution. In ten months after the amputation I saw him again, and his health seemed much better, since he had got rid of the incubus of the disease; the wound had nearly healed; there were two sinuses, one before and another behind, but the appearance was favourable. Since that time I have not had an opportunity of seeing him. Though ulceration of the cartilage of the shoulder-joint is often the effect of inflammation of the synovial membrane, and is also connected with scrofulous disease, it occurs sometimes as a primary disorder. I have not seen it in the shoulder, but I have in the knee; yet I have no doubt it has occurred. When it occurs in the shoulder, it is generally connected with some form of rheumatic inflammation in the articular textures.

The patient has pain in the shoulder, small at first, but increasing for months, and is worse at night, and affects the muscles of the limb, rendering the patient weak. When you press the articulating surfaces against one another there is an aggravation of the pain, indeed by every kind of motion; the pain is referred chiefly to the joint, but it extends down as far as the hand. There is no swelling of the joint, but a decided diminution. The deltoid muscle wastes, and you know this lessens the size of the joint. This smallness of the shoulder corresponds with the flattening of the nates in diseased hip. I suppose this disease would go on to the formation of matter in the joint; but the cartilage does not ulcerate, and the joint may become ankylosed, without abscess, and the patient get well. When this kind of caries affects the spine it may destroy many of the vertebræ, and yet no abscess exist.

The treatment of this form of disease in the shoulder does not differ from the same form in the knee; I therefore refer you to what I have written on that subject. I may just say, keep the joint immoveable, you will do well to protect it by the leather splint; it is one of those cases where counter-irritation is useful, and therefore I have sometimes applied a blister; but I think caustic issues are preferable, one in front and one behind,

to be kept open, not with peas, but by rubbing with caustic potash; but do not harass the patient. There are constitutional remedies more important than local applications. Treat this as you would orchitis or iritis. Mercury is an important medicine. Give two grains of mercury and one of opium, once or twice in the day. If the patient be scrofulous (and it is not always the case), give sarsaparilla, 3ij. of the extract in the decoction, or mercury and sarsaparilla. You may give mercury with iodide of potassium. If you are afraid to give so much mercury as I have named, give five grains of blue pill, night and morning; or two grains of iodide of potassium, night and morning. You will not be required to maintain the use of the mercury long, not longer than ten days, or three weeks at the most. Under this treatment I have never known what I believe was permanent ulceration of the cartilage of the shoulder fail to give way in a certain time, although on recovery the shoulder will, of course, be more or less stiff.

The primary ulceration of the cartilage of the shoulder assumes two forms, as in other joints, and is sometimes acute and sometimes chronic. It is especially in its acute form that mercury is indicated, and, when chronic, sarsaparilla helps very much to put an end to it.

The shoulder may be the seat of malignant disease. A patient was admitted to this hospital, complaining of pain in the shoulder; the pain was slight and the shoulder very large; the pain was not much aggravated by motion, except when the arm was elevated to a right angle with the trunk, then much pain was experienced. She was here for some time, and went out. The nature of the disease was not then understood; she was readmitted. There was now not much pain, but the joint was much enlarged; soon after she had erysipelas and died. I examined the shoulder carefully; the head of the humerus was much attenuated, and much like a thin membrane. When the cartilage was pulled off, the cancellous structure of the bone was quite abnormal; hardly any earthy matter left in it, quite vascular, and looking to the eye like a part affected with medullary disease—fungus hematodes. This substance, over the greater tuberosity, had made its way to the projection on the inside of the scapula, and perhaps this was the cause of that pain which was felt when the elbow was raised. Behind the parts I have mentioned, the bone presented another appearance of disease—it was hard like scirrhus; the scapula was free from disease. Perhaps, if the limb had been amputated, there would have been little chance of cure with so much tendency to erysipelas; but what should have been done had there been no erysipelas? I think amputation would have been right. We judge of what will take place by what has taken place. A young lady had pain in the shoulder, for which she had consulted several persons and tried many different remedies. She did not apply to me till twelve months after the disease was first remarked. She had considerable disease of the head of the humerus. I handled the head of the humerus and moved it in every direction, showing no disease of scapula. Sir A. Cooper and Mr. Key saw her, and we all recommended amputation. We removed the shoulder-joint, and the capsular ligament was in its natural state, but the head of the bone was much enlarged. On making a division of the enlarged head of the humerus, it was found that there was a large tumour, the earthy matter of bone had disappeared, and there was fungus hematodes.

There was, in this case, one feature rendering it favourable for an operation—the whole of the seat of disease was removed, it terminated very well, and no return of disease has taken place ten years after. Now, there is a class of cases of disease of the shoulder-joint, concerning which you will often be consulted in private practice, with the pathology of which I cannot profess myself positively acquainted. It happens that we cannot examine the body, as patients do not die of it. You may know it by an assemblage of symptoms,

Composition of the soluble salts.

	Man.	Dog.	Cat.	Horse.	Ox.	Calf.	Goat.	Sheep.	Rabbit.	Pig.	Goose.	Hen.
Alkaline phosphates	0.8334	0.7809	0.607	0.844	0.468	0.937	0.408	1.395	0.437	1.285	1.135	0.945

MM. Andral, Gavarret, and Delafond have likewise given us the results of some analyses of the blood in various domestic animals:—

Name of Animal.	Fibrine.	Globules.	Solid matters of serum.	Water.
4 stallions, used for heavy draught	4.5	104.5	81.3	806.7
13 stallions, used in light draught	3.9	102.3	82.1	811.7
6 oxen, used in draught	3.6	97.4	85.8	813.3
6 milking cows	3.8	119	86.8	807.5
2 pigs, from two to six months old	4.6	105.7	80.1	809.5
2 goats	3.2	101.4	91.4	801.0
6 rams and 25 sheep of various cross-breeds	3.0	101.1	82.1	813.5
4 male lambs and 1 female of the merino breed, from three to ninety-six hours old	2.2	107.5	72.8	817.7
3 rams, of English breed	3.0	92.6	94.0	810.4
10 sheep do. do.	2.6	95.7	91.9	809.8
16 dogs, of various species	2.1	138.3	75.5	774.1

MM. Andral and Gavarret have deduced from numerous experiments, that the blood of each animal offers a mean constitution which is peculiar to itself. These authors also state, that the fibrine is more abundant in the carnivora than in the herbivora; that it exists in but feeble proportion in the newly-born animal; and that it is lowered in amount during gestation, but rises again after parturition. The globules present their maximum in carnivorous animals, and their minimum in herbivorous. The albumen of the serum appears to follow the same law as the globules. The following table further shows that diseases alter the blood of animals in a similar manner, and according to the same laws, as in man.

Pathological Blood in the Sheep, according to MM. Andral, Gavarret, and Delafond.*

URINE.—While examining the phenomena of respiration, we considered the lung as an organ of excretion, and stated that it was charged with eliminating from the economy certain gaseous products, with which the blood becomes loaded during the vital processes. The kidneys, viewed in the same light, free the blood of certain liquid matters, or such as are soluble in water, and which pass in excess into the economy by the digestion of the aliments, or else which result from the daily accomplishment of the phenomena of life itself. This circumstance explains why the urine, from the remotest antiquity, should have attracted the attention of physicians, who have sought, by its aid, to characterize certain affections, attempting to base them upon the physical properties of this fluid. It was not, however, until the middle of the seventeenth century, that the urine was studied in a chemical point of view. The first examination of this fluid, which was at all deserving of attention, is due to the younger Rouelle, who discovered urea in the human urine, and benzoic or hippuric acid in the urine of the herbivora. Scheele soon afterwards recognised in this fluid the presence of uric acid, to which he attributed the formation of calculi and of gravel. More recently, Wollaston analysed the different kinds of calculous deposit, and laid down a complete history of them. Cruikshank, about the same time, made a comparative analysis of normal and of diabetic urine, in the latter of which he pointed out, for the first time, the presence of saccharine matter; he, moreover, demonstrated in urea the property it possesses of combining with nitric acid. Fourcroy and Vauquelin published, a short time afterwards, an elaborate and important work on the urine, dwelling particularly on urea and the urinary calculi, and

entering minutely into the fermentative process of urine. M. Thénard called attention to the fact, that the acid, by means of which the earthy phosphates are maintained in solution, is a body of an organic nature. M. Berzelius has discovered that this principle is not acetic acid, as was generally thought, but that it is lactic acid; he was the first to give a complete analysis of normal human urine. Proust has also published some elaborate researches on the urine. His observations have been, in great measure, confirmed by Liebig, who has added considerably to our knowledge on this subject.

In entering on the consideration of this fluid, we will first describe it in its normal state; and it will be easy for us, subsequently, to add to this knowledge a description of the changes which the urine experiences in certain diseases, as well as that of the variations which it presents in different animals.

In the normal state, human urine is a limpid liquid, of a colour varying from a clear yellow to a yellowish-brown, and having a salt, disagreeable, and bitter taste. It possesses a characteristic stale or urinous odour, which disappears on its becoming cold, but is again engendered by moderately heating it. Its density varies greatly; most frequently it ranges from 1.015 to 1.030. It has an acid reaction on litmus-paper. If left to itself for several days, it becomes changed in colour, throws down some salts, becomes alkaline, and gives out an ammoniacal and repulsive odour.

Heat does not coagulate urine; if it be subjected to evaporation, and the residue be distilled in a retort, we obtain carbonate, acetate, and hydrochlorate of ammonia, as well as an inflammable oil. At a very elevated temperature, it yields a small quantity of phosphorus.

The acids, in general, have no action upon urine, excepting oxalic acid, which precipitates its lime. The alkalis and some salts form with it precipitates of a variable nature, the production

of which will be better understood upon examining the analysis of normal urine, as given by M. Berzelius. It is as follows:—

Water	933.00
Urea	30.10
Free lactic acid	..
Lactate of ammonia	..
Animal matter, soluble in alcohol	17.14
Extractive matters soluble in water	..
Uric acid	1.00
Mucus of the bladder	0.32
Sulphate of potass	3.71
Sulphate of soda	3.16
Phosphate of soda	2.94
Biphosphate of ammonia	1.65
Chloride of sodium	4.45
Chloride of ammonium	1.50
Phosphate of lime and magnesia	1.00
Silica	0.03

1000.00

The nature of the salts, which M. Berzelius has discovered in the urine, will show at once the character of the reagents which will precipitate it; these are—ammonia, nitrate of silver, baryta, lime, oxalic acid, the salts of lead, &c.

We should not forget, moreover, that there exist in the urine extractive matters, which may also furnish precipitates with the salts of mercury, and with the sub-salts of lead, &c. These matters are but little known.

If a large quantity of alcohol be added to fresh urine, a precipitate of a very complex nature is formed: for, besides the earthy salts, the phosphates and sulphates, which the alcohol is unable to retain in solution, this precipitate contains uric acid, mucus, and probably a small portion of extractive matter.

Tannin renders urine cloudy, by combining with the mucus and with a portion of the extractive matter; the muddiness is at all times very slight. If it be much marked, we must attribute it to the accidental presence of albumen.

ORIGINAL CONTRIBUTIONS.

THE CAUSES OF SUDDEN DEATH.

By MALCOLM HILLES, Esq.

It is somewhat extraordinary that, amidst the various treatises that have appeared of late years on the several divisions of medical science, not one has been devoted to the consideration of the causes of sudden death, or, so to speak, of the physiological and pathological conditions which induce a sudden cessation of the vital powers.

And yet few subjects can be more interesting, certainly none more important, or more likely to command professional attention.

As living, moving, and thinking beings, the phenomena which life presents are peculiarly interesting. Who can behold it, even in the vegetable world, where traces of it are feeble and imperfect, with indifference? Who can examine it in man, the most perfect of animals, without admiration? From the delicate lichen that can scarcely be said to live, to man himself, every step, as it were, to vital perfection, excites the wonder as well as the attention of the zealous inquirer. The most indifferent cannot view the subject unmoved, and almost involuntarily admires why or by what means such extraordinary results are obtained.

If the phenomenon of life, and the laws which govern its production and support, be interesting, the study of the causes which lead to its decay and dissolution cannot fail of awakening attention. It is true that it is a more pleasing task to contemplate the perfection of structure that maintains the vital principle, than the imperfections which cause its ultimate extinction, as the mind naturally inclines to what is perfect and beautiful; yet these imperfections must be interesting to the philosophic mind, as portions of that great chain of events which Nature has

* For an insight into the microscopical characters of the blood, the reader should consult the writings of Hewson, Donné, Mandl, and Henle.

fabricated, and which lead to the ends which she designs to consummate.

Indeed, to the medical profession, whose duties are rather directed to the prevention of death than to the maintenance of life, abstractedly considered, such an inquiry is the more important, perhaps, of the two; to all individuals, as deeply interested in the successive changes which the body undergoes from "the cradle to the grave," it affords much room for observation and reflection.

I must do the profession to which I have the honour to belong the justice to state that the question of the causes of sudden death has met with considerable attention from them, and that various observations have been published, from time to time, by its members on the subject; but these are much scattered and require collection: this is indeed what I propose to do, adding such remarks as may appear to me necessary to connect them together, and elucidate such as I may consider not to furnish sufficient for a general treatise.

How many die suddenly! and yet how few take the trouble of inquiring into the causes of such deaths. Some, more curious than others, may hazard a question on the subject; the reply is most probably "apoplexy"; and yet I have no hesitation in asserting that not half of the deaths attributed to apoplexy are really produced thereby.

In support of this assertion it may be mentioned that M. Devergie, the medical director of the Morgue, in Paris, has found the causes of death, in forty cases carefully examined by him, to be—Apoplexy, with a clot in the annular protuberance, 1; meningeal apoplexy, 3; serous apoplexy and pulmonary congestion, 2; congestion of the brain and spinal marrow, 3; pulmonary congestion, 12; pulmonary and cerebral congestion, 12; hæmatomesis, 2; syncope, 3; rupture of the heart, 1; rupture of the pulmonary artery, 1.

Thus, out of the above forty cases, but nine could be referred to apoplexy, twelve to pulmonary and cerebral congestion combined, the remainder had no connection whatever with the apoplectic disease.

Again, in "Guy's Hospital Reports," April, 1845, Dr. Francis found, in nineteen cases of sudden death recorded by him, but six cases connected with cerebral disease: of these, two were from rupture of arteries at the base of the brain, one from violent congestion of the brain with thoracic obstruction, one from chronic disease of the arteries and substance of the brain, two from epilepsy.

How culpable is this indifference, this neglect, especially when we reflect that the treatment to be persisted, in many of these cases, is widely different; nay, that the treatment which is necessary in one may be fatal in the other.

Death may be defined to be a deprivation of life, or rather a cessation of the functions on which life depends, and thus indicates a negative rather than a positive state of being. We die, that is, we cease to live; the principle which imparted life to our frame has ceased to inhabit this; and it consequently returns to its original condition in the inanimate world. The moment death takes place, or life ceases, those changes commence in the inanimate body which are ultimately to resolve it into the gaseous fluid or solid materials from whence it derived its existence; the change is but one of elements: the body ceases to live, but not to exist; it still exists in the material world around, and again takes its part in those elements whence it was formed.

No action or influence to which human ingenuity may expose it can cause its annihilation; air, earth, fire, water, all can only change, none can destroy, save Him who created. Life depends for its integrity on the perfect performance of certain functions, which are therefore denominated the *vital functions*; these, in their turn, depend for their continuance on the perfect connection of the organs from whence they derive support; life, therefore, depends on the perfect organization, and can no more exist without it than day without light, or any material object without the matter of which it is composed.

But organization does not necessarily produce or create life; the body often presents, after death, to all external examination, the most perfect organization; and yet life has fled; the tree struck by lightning frequently presents no traces of disorganization, yet it has ceased to live, and soon perishes. There is a vivifying principle independent of organization, and which is as necessary to the animating of this, as its perfection is to the maintenance of life. There is no instance of life being produced without life.

I shall not wander into a metaphysical discussion, however interesting this might be, but proceed to the physiological consideration of the subject.

The *vital functions*, or the functions on which life depends, are the nervous, the circulatory, and the respiratory: the organs on which these respectively depend are, the brain and nervous system, the heart and vascular system, the lungs or pulmonary system.

These functions are usually classed, after the example of Bichat, into—1, the functions of *animal life*, or those performed by the brain and nervous system; 2, the functions of *organic life*, or those of the organs of circulation and respiration.

An arrest of the functions of any one of these three great *centres of life* will soon cause the cessation of the others, and thus produce the death of the individual. If the organs of respiration cease to act, the blood is no longer arterialized: impure blood is sent to the brain and nervous system; this fails to produce the nervous excitement necessary to cause or sustain the muscles or mechanical agents which maintain the mechanical and chemical action on which life depends; these, therefore, become paralysed, and complete death is soon the result.

If the circulation be arrested by the bursting of either the heart or blood-vessels, or other cause, the same result is produced, but more rapidly, and in a somewhat different manner. Here, the cause of death is negative, not positive, and consists in the absence of all blood from the brain and vital organs; the functions of these, therefore, cease, and death rapidly ensues.

As the nervous system consists of two somewhat distinct yet intimately connected portions, namely, the cerebro-spinal and sympathetic—and as these preside, the first over the animal, the second over the organic, life of the individual—the functions of either of these may be destroyed, independently of the other. In apoplexy, for example, the animal life is frequently extinct for some time before the organic life ceases; and in some sudden nervous affections it is reasonably inferred that the organic life ceases before the animal is affected: so intimately connected, however, are these two, both in function and structure, and in that general control of all the actions of both animal and organic life so necessary to their perfection, that it is impossible for one to be wholly extinguished, without the other immediately feeling the result, and soon participating in the consequences.

Let us take, for example, the case of apoplexy already mentioned. In this the more evident symptoms of animal life, such as sensibility and voluntary motion, may be absent, and these altogether destroyed for a length of time, without serious result (a); yet animal life is evidently not wholly extinguished so long as respiration and circulation continue: both of these functions, although principally supplied by the sympathetic system of nerves, being indebted for their continuance to the agency of the pneumo-gastric and other nerves derived from the cerebro-spinal system, and which appear to exercise an influence on those of a distant and, it may be called, superior character to that which is connected with the mechanical performance of these functions; for the performance other respiratory nerves are destined.

(a) Sir A. Cooper relates the case of a sailor, who remained for twelve months in a state of stupor from a depressed portion of bone.

In the remarkable case of the Hon. Colonel Townshend, related by Dr. Cheyne, it would appear that organic life had become extinguished without animal life participating in its destruction, as this individual maintained his power of voluntary action, and exercised this by rallying the functions of organic life into operation.

In syncope, or fainting, both the animal and organic life seem to cease whilst the fit continues. It is stated by some that the circulation and even respiration proceed in these cases, although not so evidently as to be apparent either to sight or touch.

Many cases, however, are on record in which these functions were suspended for a considerable time, and yet life was not extinct, the individuals having been restored, and continued to live, some for many years after. This state of existence is somewhat analogous to that of the vegetable kingdom, in which life is present, although both sensibility and visible motion are absent. The following cases of suspension of the usual symptoms of life are most important and interesting.

Pliny, in a chapter entitled, "De his qui elati reviscerant," relates the case of the Roman consul Avicular, who, being supposed dead, was conveyed to his funeral pile, where he was re-animated by the flames, and loudly called for succour, but, before he could be saved, he was suffocated. Boutrier (a) relates an instance of a young woman upon whose supposed corpse an anatomical examination was about to be made, when the first stroke of the scalpel revealed the truth.

Numerous other cases are recorded, in which all life was suspended for several days, save that analogous to vegetable existence, and which evidenced itself in preserving the body from decomposition, and in sustaining a moderate temperature.

Some will perhaps assert that organic life, in the actions of respiration and circulation, must have existed in these cases, but so freely as not to be ascertained by external examination. To this there is but one reply, namely, that, as we cannot resort to internal examination, the matter must rest unsettled. We do not see why life may not be feebly supported in man, as in the lower tribes of animals and vegetables, without manifesting any evidence thereof beyond, as already stated, that of resisting decomposition and sustaining a moderate temperature; but, as this requires some action, we must acknowledge the existence of this in the cases cited, although so feeble as to elude observation. The remaining organs and functions, although necessary to life, contribute to it only indirectly, or in a secondary form, thus, for example:—

The *bony system*, or *skeleton*, is by no means essential to life, even in the highest classes of animals, in man himself. In the disease of rickets the bones become softened, without danger to the life of the individual; although this softening seldom affects the whole osseous system, its influence is sufficiently extensive, in many instances, to support this conclusion. The bones are frequently fractured, without life being in the least impaired thereby; indeed, if it were possible for every bone in the body to be fractured, without producing a shock on the nervous system, the patient would suffer but little thereby beyond the inconvenience arising from such extensive injuries; the great vital functions would continue to support life uninterruptedly, the only one likely to be in the least impaired being that of respiration, which would suffer from the injury done to the parts engaged in producing the mechanical act of respiration.

The *osseous system*, being essentially necessary to locomotion, contributes but little to the integrity of the vital functions, its connection with these affording them rather protection than ministering to the completion of their functions.

Nor is the *muscular system* much more sub-

(a) "Dissertation sur l'Incertitude des Signes de la Mort," &c. Cyclop. of Medicine, vol. iii., p. 316.

servient to the integrity of the functions of life; its sole influence on these arises from its being the powerful mechanical agent employed by nature in the circulation of the blood, and in the performance of the act of respiration; thus muscular fibres are found in the heart, the smaller arteries, and some of the larger veins: but their use in these is simply to propel the blood onwards to its destination; in like manner muscular fibres constitute the great bulk of the muscles of the respiration, but they do not constitute in any way to the perfection of the function, except as mechanical agents.

Their influence, however, on the perfection of these functions is not to be altogether disregarded, as we shall have occasion to observe hereafter, that a cessation of life is often suddenly caused by a morbid condition of the muscular system, existing in it, or imparted to it, through the agency of the nerves.

The various functions of digestion, secretion, and excretion are not of such immediately-essential nature to life as to call for particular observations at present; no case, I believe, of sudden death has ever occurred from a stoppage of any one of these functions; indeed, the most healthy individual presents daily examples of a temporary cessation of one or all of these functions, without the notice of, much less any injurious effect on, the person.

But how different is it with regard to the three great functions, which are justly styled the *vital functions*! a momentary cessation of any one of these instantly places the life of the individual in danger; a more continued arrest annihilates life beyond the power of all human efforts. How admirable that structure, then, which, composed of the slenderest threads, keeps on its way through tens of thousands of hours, through some thirty millions of moments, without one instant's interruption! How wonderful the contrivance that pulsates upwards of one hundred and ninety millions of times in a life of ordinary duration, without, perhaps, one interruption even for a second! How perfect the design that contributes so effectually to such an end!

Although sudden deaths are of such frequent occurrence, and excite so much attention, speaking physiologically, they rarely happen, except from accident, as they are almost uniformly the result of disease, that has commenced some ten or twenty years previously, and has been, during this length of time, engaged in producing the fatal result. How, therefore, can we call such a death sudden? It is true that life appears to us to be suddenly extinguished, but nothing is more certain than that this extinction of life had commenced many years previously, and that, so far from the person perishing suddenly, he had "begun to die," as it were, some twenty or thirty years before.

Although a startling and a somewhat unpleasant fact, it cannot be contradicted that most persons beyond the age of sixty, many past fifty, or even forty, bear with them the foundations of the disease, which is one day or other to terminate their existence: the heart, the arteries, perhaps the lungs or other viscera, are the seats of this morbid affection. I have now examined many hundred bodies, and, speaking from recollection, I do not think I ever met with one past sixty years of age in which the arteries were free from disease; in most of them extensive ossification existed. This condition is exemplified, even in the living subject, by a peculiar whiteness of the skin and hair.

As it will appear more regular, and doubtless prove more satisfactory, as well as convenient, to commence the consideration of the causes of sudden death by first examining into those connected with the function of respiration, I shall adopt that course, then proceed to

2. Those attached to the circulatory system.

3. Those connected with the functions of the nervous system; and conclude with

4. Remarks on cases of sudden death, the causes of which are as yet involved in doubt.

The cases of sudden death which are caused by arrest of the respiratory function may be classed into

1. Those which occur where lesions or morbid alterations of the organs of respiration have existed and contributed to the fatal result.

2. Those which take place in cases where either no lesions or morbid alterations have existed in the organs of respiration, or, if present, have not contributed to the result.

3. Those which are caused by direct violence, injury, or accident.

We shall proceed to consider—

1. The physiological causes of sudden death in such cases as occur where lesion or morbid alterations of the lungs have existed and contributed to the result.

The diseases to which the lungs and respiratory organs are subject are supposed to be less frequently productive of sudden death than those of either the organs of circulation or of the nervous system. Most pulmonary affections run through a course of longer or shorter duration under the observation of the physician and the patient's friends; bronchitis, pleuritis, pneumonia, pulmonary consumption, are all, even in their most acute forms, of sufficient duration to forbid the application of the term sudden death to their fatal terminations.

It is remarkable, however, that death takes place much more frequently than is supposed from lung affections; even in pulmonary consumption, which is usually a protracted disease, sudden death is by no means uncommon.

Sir James Clark, in his very excellent work "On Pulmonary Consumption" (a), observes as follows:—

"It occasionally happens that death occurs very suddenly in the advanced state of the disease. The patient does not appear worse than he has been for some days, when, while sitting up, he suddenly falls back and expires. Examination after death does not always enable us to explain this sudden cessation of life. Louis gives two cases, in one of which oedema of the glottis appeared to be the cause, and in the other a rapid hepatization of a large proportion of the lungs; but neither of these pathological lesions could account for the sudden termination to which I allude.

"Among the causes of sudden death pulmonary hemorrhage may be mentioned, as it is occasionally so profuse as to prove fatal in a few minutes. In such cases a considerable artery is opened, by ulceration, in the progress of the tuberculous disease."

The sudden fatality which thus attends some cases of consumption, or phthisis pulmonalis, demands our attention for a few moments. To what are we to attribute it? In which of the three great centres of life does death commence to extend its baneful influence over the individual?

The *post-mortem* examinations, as well as the symptoms previous to death, clearly show that the respiratory organs were not so much affected as to interfere seriously with their function; death, therefore, can only be referred to the nervous or circulatory system; but there is nothing to lead us to the opinion that this latter is at fault: the former must be, then, the system in which death commences. And to this supposition we are strongly led by the recollection of the feeble state of the nervous energy (not mental force) which exists in most cases of consumption. How easily wearied are the limbs! How soon is the physical strength exhausted! How prone the patient to fits of weakness, if not of fainting! These indicate a deficient nervous energy.

On the occurrence of some unusual exertion, the nervous energy is overpowered, the patient faints, the heart ceases to beat, the respiration stops; as yet the patient is not "dead, but sleepeth." At this critical moment the application of some stimulant may, and frequently does, set the vital machinery again in motion; the want of it decides the struggle, and death assumes his sway.

(a) "On Pulmonary Consumption." By Sir James Clark, M.D., F.R.S., &c. Sherwood and Co., London, 1835. P. 163.

I feel persuaded that many cases of this nature have been lost from want of this mode of treatment, or from the adoption of that *refugium peccatorum*—the *dernier resort* of all bad practitioners, in extreme cases—the lancet.

Here I must observe that the profession should set its face against the vulgar prejudice of trying what bleeding may do in such cases, on the plea that it can do no harm. It may do harm, and should not be practised: the man who thus practises is unworthy of following the profession he has adopted. (a)

The disease, if it can be called so, of the lungs which appears to be most frequently productive of sudden death is *pulmonary congestion*, or *pulmonary apoplexy*. Thus, of the forty cases of sudden death, as before related, examined at the Morgue by M. Devergie, twelve arose from this affection, twelve from pulmonary congestion and cerebral congestion, two from serous apoplexy and pulmonary congestion. It may be presumed that one-half of these deaths were produced by pulmonary congestion. Of the nineteen cases recorded by Dr. Francis, five were referrible to pulmonary affections generally.

At the same time it must be observed, that pulmonary congestion is an affection which may be produced after death, or so close a resemblance thereto may be induced as to be incapable of distinction. Thus, for example, there is in most bodies a tendency to accumulation of blood in the lungs in the last moment of, or immediately after, death; this is particularly the case where the left ventricle continues to contract after respiration has ceased, the blood being thus forced on the venous and pulmonary system.

The position of the body too, may tend to this appearance, the blood obeying the laws of gravity. When the lungs are free from disease, the circumstance of the blood being confined to the posterior part of these organs will assist in forming our opinion; but there is no reason why the blood should not gravitate equally after pulmonary congestion, where the lungs are otherwise healthy. There can be no doubt, where the whole tissue of the lungs are found gorged with blood.

The structure of these organs, the reticular cellular tissue of the infinite ramifications of capillary vessels, of which they are composed, dispose to this affection on any sudden exertion, as, independently of a large vessel being ruptured, the whole capillary system, both venous and arterial, may pour out their blood into the parenchyma of these organs, as frequently occurs in the cerebral organs.

It may be doubted, therefore, if all the cases of sudden death referred by M. Devergie to pulmonary congestion shall be assigned to this cause, especially as in many, it is to be presumed, he was unable to obtain any previous history. The pulmonary congestion was doubtless the consequence, not the cause, of death in some. A sufficient number, however, were beyond all question referrible to this affection, to entitle it to be regarded as frequently productive of sudden death.

Here the lancet may be used without being abused, as no means are so likely to afford relief. The use of stimulants would not be injudicious, with a view to excite the renewed action of the muscles of respiration, the heart, &c.

(To be continued.)

(a) Some years since I was called to a gentleman who dropped dead in the street. I found that he was past all hopes, and that he had to all appearances died from the bursting of some bloodvessel internally, his face being perfectly blanched; I therefore pronounced such to be the case, and refused to bleed him further. Some ten or fifteen minutes after, a medical practitioner, but I believe an unqualified one, saw the body, made a cut in the arm, and thus left the mark of his attendance. He was summoned to the coroner's inquest, was paid for his trouble, whilst I was left to console myself with the philosophical reflection, "that virtue is its own reward."

FACTS AND OBSERVATIONS.

as to the relative Value of Mesmeric and Hypnotic Domia, and Ethereal Narcotism, for the Mitigation or entire Prevention of Pain during Surgical Operations.

By JAMES BRAID, M.R.C.S.E., &c.

"The following table shows the curious fact, that,

Patient.	Disease.	State of Pulse.			Operation.
		Before.	During	Immediately after.	
Nilmoney.	Tumour.	84	124	Natural.	Apparently painless.
Ditto.	Dressing changed on September 12.	80	108		
Dohman.	Tumour.	72	72		Doubtful.
Jahinodan.	Excision of thickened prepuce.	60	60		"
Ranchund.	Tumour.	68	68		"
Hyder Khan.	Amputation of thigh.	108	112	100	Apparently painless.
Murali Dass.	Tumour.	68	108	72	

This acceleration of the pulse, in cases which showed no evidence of suffering pain during the operation, whilst it remained unaltered in those cases which were accompanied with writhing and distortion of features, seems to have puzzled and perplexed both Dr. Esdaile and the committee, as it may many others, who would naturally have expected the very opposite results. The fact is very easily explained, however, and the solution of this apparent anomaly will at once suggest itself to all who have read my little treatise on Hypnotism with attention. In the former cases the stimulus of the knife has excited a greater or lesser degree of rigid catalepsy, which is always attended with acceleration of pulse, generally in the ratio of the intensity of the rigidity (and it also suspends motion); whilst in the latter cases, accompanied by distortion of features and jactitation of the limbs, there being no rigidity of muscles to obstruct the transmission of blood through the limbs, there would not necessarily be any acceleration of the pulse, unless from mental emotion. The tranquillity of the pulse in these cases, therefore, was the surest possible indication that the patients spoke the truth in declaring that they had felt no pain. The jactitation of the limbs, and convulsive movements of the muscles of the face, in the latter, as well as the rigidity in the former cases, might all arise as reflex or automatic actions, of which the brain might take no cognizance, as is well known to every physiologist, and is daily witnessed during the sound conscious state of nervous sleep.

Dr. Esdaile considered much less blood was lost by patients who were operated on during the mesmeric sleep; but three of the four medical members of the committee expressed as their opinion, that there was no material difference observable. Neither did the medical members consider that the after-treatment of the patients was in any degree ameliorated, or the cure accelerated, by the operation having been performed in the mesmeric sleep.

The following is the only case to which the committee attached any importance to renewing the dressings of sores during the sleep:—

"In Ranchund, an examination of the wound, of a peculiarly painful nature, was required (dressing) involving two separate incisions; just as the first was completed (it lasted about a quarter of a minute, and caused writhing of the body and distortion of the face) he awoke, and, on proceeding to the second step, he shouted aloud in pain and terror, and struggled so violently that the operator could not proceed." This seems pretty conclusive evidence, that whilst he was a person of keen feelings, the induced sleep had saved him much suffering during the first incision. It also tends to support the truth of his statement, as to having suffered no pain when first operated on, on the 13th of September. It strikingly proves, moreover, the superiority of sleep thus induced for such purposes from that induced by an opiate, as the following case will show:—

"The committee, having adjourned to the Native Hospital, inspected No. 4, Neechul, upon whom Dr. Jackson operated, removing the hypertrophied prepuce at one stroke.

"Ninety drops of laudanum had been admin-

istered half an hour previously, and the patient was sound asleep when operated on: pulse 80. "At the moment of operating, he shouted aloud, struggled violently, drew up his legs, and kicked hard: pulse rose to 120; he continued to struggle for several minutes."

In paragraph twenty-seven, the committee expressed a similar opinion to that which I have already stated as my own conviction, respecting the great length of time required destroying its general applicability in surgical practice. They say— "The uncertainty of the time required in producing the intense condition of the mesmeric sleep, in the majority of the cases now under notice, appeared very unfavourable to the general introduction of mesmeric manipulations in the practice of surgery, especially in hospitals. But Dr. Esdaile states positively, that by frequently changing the mesmerizers, and performing the manipulations without interruption, the same results may possibly be produced in one day, which would, in the manner pursued before the committee, have been necessarily extended over several days. In the cases of Hyder Khan and Murali Dass, several mesmerizers were successively employed, and the result seemed to the committee corroborative of Dr. Esdaile's statement.

"The committee further apprehend (the report goes on to state) that a serious practical obstacle to the universally useful application of mesmeric processes exists in the resistance to the sleep, which, Dr. Esdaile acknowledges, is given by cough, by pain, by mental excitement, by fever, and by the sinking state of the vital system induced by protracted and dangerous diseases."

I can state, as the result of my own experience, that patients with restless and excitable minds are generally, if not always, difficult to be reduced into a deep state of nervous sleep. In cases of fever, so long as it is possible to arouse and arrest the attention of the patient, he may be affected; I have failed, however, with one of the most susceptible subjects I ever met with, when in a state of such profound delirium from fever that the attention could not be arrested and fixed: a clear proof that hypnotism is as much a mental as a physical influence.

The fears expressed in paragraph 30, that the repetition of the processes may bring the nervous systems of patients into a morbidly impressible condition, which might render them liable to numerous nervous maladies, I feel assured, from very extensive experience, is a groundless fear, provided the patients are treated with care and judgment. In the whole course of my experience I have met with no such untoward result, although I have hypnotized some patients daily for several months successively.

I most heartily concur in the just tribute of praise awarded to Dr. Esdaile in the concluding paragraph of the committee's report:—

"The committee are unanimously of opinion that great credit is due to Dr. Esdaile for the zeal, ability, and boldness with which he has taken up and pursued this inquiry." They further add:— "His sphere, however, has been hitherto limited, but the committee hope that his further investigation may be extended to medical as well as surgical cases, to European as well as native patients, and

to the elucidation of the several questions which have been adverted to in the course of this report."

In the Deputy Governor's reply to the above report, he says:—"So far has the possibility of rendering the most serious surgical operations painless to the subject of them been, in his honour's opinion (it was written by the secretary), established by the late experiments performed under the eye of a committee appointed for the purpose, as to render it incumbent on the Government to afford to the meritorious and zealous officer by whom the subject was first brought to its notice, such assistance as may facilitate his investigations, and enable him to prosecute his interesting experiments under the most favourable and promising circumstances.

"With this view his honour has determined, with the sanction of the Supreme Government, to place Dr. Esdaile for one year in charge of a small experimental hospital, in some favourable situation in Calcutta, in order that he may, as recommended by the committee, extend his investigations to the applicability of this alleged agency to all descriptions of cases, medical as well as surgical, and all classes of patients, European as well as native. Dr. Esdaile will be directed to encourage the resort to his hospital of all respectable persons desirous of satisfying themselves of the nature and effects of his experiments, especially medical and scientific individuals in or out of the service." Medical officers of the presidency are also to be appointed as visitors, to inspect the proceedings of Dr. Esdaile, and report thereon to the Government, but without interfering with the doctor's proceedings."

Here, then, we have an example of the most judicious, praiseworthy, and enlightened conduct, both on the part of the Government and the committee, which has ever been recorded, in connection with this highly interesting inquiry. It is conduct not only deserving of all praise, but also worthy of universal imitation. Extending the inquiry and treatment to medical cases, I feel confident, is a movement in the right direction, as it may be rendered of far more avail for the relief and cure of disease, than for suspending the anguish of painful surgical operations; and the latter application is the less important now that we can achieve the like purpose so much more generally and rapidly by ethereal narcotism. That the latter process may also be used with advantage in the treatment of various forms of disease I have no doubt. Indeed I have been in the habit of using the fumes of ether for such purposes, in my own practice, for the last thirty years. Still I feel well assured, from what I know of both methods, that whilst the ethereal narcotism is likely to prove most available for preventing pain during surgical operations, it will never be rendered so available for the relief and cure of disease as mesmerism and hypnotism, when the latter are judiciously and skilfully managed. I presume it is scarcely necessary for me to add, what must be apparent to every reflecting person, that practical experience is as requisite for the successful treatment of disease by hypnotism or mesmerism, as by any other mode of cure.

In theory I entirely differ from Dr. Esdaile. He is a mesmerist—that is, he believes in the transmission of some peculiar occult influence from the operator to the patient, as the cause of the subsequent phenomena. He has entirely failed, however, in adducing any new or additional evidence in support of this position, which had not been adduced before by European mesmerists; with which opinions I am entirely at issue for reasons which are well known to your readers, from my previous contributions to the *Medical Times*. In these papers I have illustrated and explained, as the ground of my dissent from the occult-influence theory, that all the well-ascertained phenomena of mesmerism can be equally, readily, and more satisfactorily explained, without the aid of any occult or esoteric influence. It is gratifying to me to be able to add, in support of my opinion on this point, that since the publication of my observations "On the Power of the Mind over the Body," I have had the honour to receive numerous letters from some of the most eminent members of the profession and of general science, expressive of their entire concurrence with my

views of the nature and cause and extent of mesmeric phenomena generally; and also of my mode of explaining the extraordinary phenomena adduced by Baron Reichenbach, as proof of a "new imponderable." On this last point I have only met with one of two dissentients, and these were parties who were previously strongly committed to the mystical notions of the mesmerists.

Dr. Carpenter, in the third edition of his "Principles of Human Physiology"—one of the most perfect and valuable works on physiology extant—has fully admitted the reality and peculiarity of all the mesmeric phenomena which I contend for. He says to that extent he considers they have "as just a title to the attention of the scientific physiologist as that which is possessed by any other class of well-established facts." Dr. Carpenter was present at a private *conversations* at my house, when he had an opportunity of investigating the phenomena most minutely; and the lucid manner in which he has described the nature and modes of inducing the genuine manifestations does him infinite credit. In respect to my mode of operating, he has done me the honour to say, at page 757, that—"He considers that this curious class of phenomena cannot be better prosecuted than by that method."

I have thus endeavoured, to the best of my ability, to submit to your readers a candid estimate of the relative value of hypnosis, mesmerism, and ethereal narcotism, for the relief and cure of disease, as well as for suspending consciousness, and thus relieving entirely preventing pain during surgical operations. I shall be glad if my public endeavours may in any degree tend to the advancement of what seems to me so well calculated to promise amelioration to suffering humanity.

3, St. Peter's-square, Manchester, Jan. 30.

P.S. Experience has proved that the fumes of sulphuric ether may be rendered available for suspending consciousness, and thus preventing pain during surgical operations, in the brute creation as well as in man. It has been used with complete success for such purposes with the dog, the sheep, and the horse, as publicly recorded. Nevertheless I do not consider it applicable to all cases indiscriminately. The use of such a potent agent evidently requires caution in many cases, whilst in others it is altogether contraindicated. I consider nothing could be more indiscreet than bringing the system fully under its influence in certain forms of cerebral disease, as well as in various disorders or diseases of the heart and lungs. In some patients, moreover, it produces much excitement in the first instance, and is long in producing unconsciousness and total loss of feeling. In certain cases this may arise from idiosyncrasy, but it appears to me that much also depends on the rapidity with which the ether is absorbed through the bronchial membrane. Where this takes place slowly, excitement is likely to result in the first instance; but where it takes place rapidly, the blood becomes quickly surcharged with the hydro-carbonaceous compound, and the narcotic effects speedily manifest themselves, and that without any marked state of primary excitement. This is what, *a priori*, we might expect, and has its analogue in the progressive symptoms of intoxication induced from slowly sipping wine or spirits and water, which produces excitement in the first place, and depression subsequently; whereas the sudden ingestion into the stomach of a large quantity of strong liquor is speedily followed by stupor of the most intense and sometimes fatal nature, without having produced any corresponding or marked primary symptoms of excitement.

I would also infer, both from what I have read and seen, that patients who are most rapidly affected experience the narcotic influence of the ether for a much briefer period than those who are more tardily affected. I think it will be found that the narcotizing influence will require about an equal length of time for its subsidence as was required for its induction: in other words, soon drunk, soon sober, and *vice versa*.

My own rule is this—and I think myself warranted in recommending its adoption by

others—always to test the susceptibility of each patient to the influence of the ether, at least once or twice, before the time when the operation is to be performed. By this means much useful knowledge is acquired regarding the idiosyncrasy of the individual case, alike valuable to the operator and patient during the important crisis of the operation. This could not be more satisfactorily illustrated than by recording the results of an operation which I performed on the 9th of the present month (February). The patient was a lady of fifty years of age, for whom I had occasion to amputate the whole of the right mamma. But for my previous knowledge of the idiosyncrasy of this patient, by experimental trials, there can be no doubt but the results would have been very different. With this precaution, however, I was enabled to perform the operation without the patient manifesting the slightest symptom of consciousness or of feeling pain, either during the operation or whilst stitching and dressing the wound. Indeed, some time had elapsed after she had been comfortably placed in bed before the patient could be made to believe that the operation had really been performed. It is quite impossible that any case could have been more complete and decisive than this, as to the power of ethereal narcotism for suspending consciousness and feeling during surgical operations; but, from peculiarities in her case, there is good reason to believe that we should not have realized the same satisfactory results had not the patient been tested previously, by which means I was enabled to determine the proper extent to which the etheralization should be carried in her individual case. Not only during the operation, but also subsequently, the symptoms were in the highest degree satisfactory, the patient having suffered in no respect whatever from the ether, either locally or generally, mentally or physically; she slept well the first two nights without requiring any opiate.

Moreover, the patient was not only spared the shock of the mental and physical anguish usually attendant on such an operation, but it was quite obvious to all present that there was much less hemorrhage than is usual in such cases. I may also further remark that the subsequent progress of the cure has been unusually satisfactory for such a subject, the wound having healed by the first intention, being entirely adherent when first examined, which was seventy-two hours after the operation. The wound was closed by six stitches of the interrupted suture, none of which had given way. Water-dressing was used, the wound being first covered by a piece of soft linen moistened with tepid water, and on this again was superimposed that excellent invention of Mr. Markwick, the "spongio piline," the whole being secured, *in situ*, by a calico roller.

My much esteemed and talented friend, Daniel Noble, Esq., surgeon, and my son, Dr. Braid, not only assisted me during the operation, but also narrowly watched the subsequent progress of the case, and entirely concur with me in all the facts and opinions above stated regarding it.

Those who allege that tetanus and hydrophobia are not likely to be benefited by ether, because they are diseases of motion and not of sensation, and because the cerebro-motory system becomes more mobile or irritable in proportion as the functions of the cerebrum become depressed, prove by such remarks that they only partially comprehend its power. The first symptoms undoubtedly seem to favour that interpretation; but let it be carried sufficiently far, and the functions of the medulla oblongata and true spinal marrow will also become implicated, so that the action of the heart and lungs may be so impaired as to endanger the patient's safety from asphyxia; and general muscular irritability may be so suspended as to afford no indication of reflex action on the application of the galvanic current. Mr. Tracy has given some interesting remarks on this point in page 258 of the *Medical Gazette*. No doubt some diseases of morbidly exalted feeling, e. g., the whole of the painful neuralgia, may be more readily affected and benefited by it, for it

is an undoubted fact that, both by hypnosis, mesmerism, and ethereal narcotism, the first indications are in the sensorium, and that the sense of pain may be gone whilst consciousness remains: so, that the patient may be sensible to temperature, sound, smell, and sight, in some cases when there remains no distinct sense of pain from severe inflictions, such as pricking, pinching, and cutting. Still we have only to increase the means, and the whole functions of the nervous system will be depressed or temporarily suspended.

It is of great importance that washed ether should always be used; and that the inhaler should be heated to the temperature of from 80° to 90°, as by this means, as pointed out by Dr. Snow, the air becomes much more highly charged with ether than at lower temperatures, and thus the patient is more speedily narcotized, and that with much less risk of primary excitement.

The proper time for commencing the operation must be determined on by the state of the pupils of the eyes, by the state of the pulse and respiration, and by the prostration of voluntary power and muscular irritability. In prolonged operations the patient should be allowed to take about one respiration of pure air for two of the etheralized air, from the period when the operation is commenced till the whole painful proceedings terminate. Of course, giving more fresh air if the patient seems to be going too deep, and more etheralized air if getting too near the conscious state.

3, St. Peter's-square, Manchester, Feb. 13.

ON NEUROMA.

(Detailed at a meeting of the Pathological Society.)

By R. ADAMS, Esq., M.D., one of the Surgeons to the Richmond Hospital.

It must be in the recollection of many of the members present, that, during the winter session 1843-4, Dr. Robert Smith brought before the Pathological Society the result of two *post-mortem* examinations he had made of patients who had died with neuromatous tumours. In these two cases which were very similar to each other, the neuromatous tumours had been visible in almost every superficial nerve in the body; they amounted to an almost countless number in each case, had existed for many years, and had been always *painless* to the patients. One of these cases had been, up to the time of the patient's death, under the care of Dr. Hutton, at the Richmond Hospital, and one of the numerous neuromas with which he was affected sprang from the centre of the right vagus nerve in the middle of the cervical region, having attained, after ten years' growth, the size of an infant's head. In the left sciatic nerve of the same patient had arisen a neuromatous tumour which extended from the lower margin of the gluteus to the popliteal region, and in magnitude fully equalled the head of the patient, an adult about forty-five years of age. The man died emaciated, with hectic symptoms, and without pain; but the exact source of the exhausting hectic was a matter of conjecture.—The second case, the *post-mortem* examination of which was reported by Dr. Smith, had been under the care of Dr. Corrigan, in the Whitworth Hospital, where he died of dysentery. It was very similar to the former case, the tumours in both being remarkable for their size and number, and not accompanied by any pains or the source of any apparent injury to the patient, further than that arising from their weight or bulk.

Somewhat different from these two remarkable cases of neuroma already brought forward will be found those which I am now about to adduce. While in the former the tumours were to be seen springing along the course of almost every nerve in the body, in the cases presently to be related it will be seen that in each individual only one small tumour appeared in the course of the one single nerve affected by the disease.

In the two former examples, again, the patients did not complain of any pain whatever in the tumours, and sought advice only on account of the

size and growing deformity which they produced. In the latter, on the contrary, the tumours will be observed to be comparatively small, but to have been accompanied with pain of the most distressing kind, and requiring for the cure of the disease the most active surgical interference.

Although the treatment demanded by neuro-matous tumours has been laid down by Sir A. Cooper, Mayo, Velpeau, &c., still it appeared to me that the relation of the three following cases, which have been under my own care at the Richmond Hospital, may not be considered uninteresting to the society. In the first, the ulnar nerve, in the second the posterior tibial, and in the third case the median, was the seat of the neuroma.

1st Case.—Owen Nolan, aged forty, was admitted to the Richmond Hospital in October, 1836, to be treated for an old stricture and a sarcocele; he had been a dragoon in the British army, but was now out of the service. While in the hospital he directed my attention to a tumour on the internal side of his right arm, a little above the internal condyle of the humerus. It was of an oblong form, about one inch and a half long, and evidently connected with the ulnar nerve, which, in the situation of the swelling, seemed to have acquired four times its natural size. This tumour appeared, on feeling it, as if solid, and was movable in the transverse direction; all this information being obtained at the expense of some suffering to the patient. He dreaded any one handling the swelling, or anything even touching it, because, at the moment of each examination, and even for a quarter of an hour after, a stinging pain was felt all along the course of the branches of the ulnar nerve. The pain was most severely felt in the fleshy portion of the palm, at the inner side where the ulnar nerve divides and its branches sink deep into the palm, as also along the sides of the little finger and ulnar edge of the ring finger.

It is, however, to be remarked, that the patient never suffered any pain in the tumour except when suddenly touched or pressed upon, and, from the situation of the disease, these were accidents which seldom occurred.

Independently of the disease, Nolan was then under treatment: for it is to be observed that his general health had suffered much while in the service of the British army in India.

He stated that while on duty he had been thrown from his horse, of which fall he still bore on his person the sad memorial, in a dislocation of his left elbow-joint, which had never been reduced; so that "*Jam fractus membra latore*;" he neither sought for any active treatment to be applied to the removal of the neuroma, nor did I or my colleagues think it right, under the circumstances, to propose any to him.

When he was somewhat relieved of the sarcocele and stricture, he left the Richmond Hospital; and, in the latter part of the year 1839, was admitted into the Hardwicke Hospital for fever, of which he died.

The neuroma was found to consist of a swelling, about one inch and a half long, of the ulnar nerve, in that part of its course situated nearly above the internal condyle of the humerus. The swelling when cut into proves to be a cyst containing transparent albuminous fluid, and formed within the neurilemma. The filaments of the nerve, separated from each other, were spread out over the surface of the cyst, and were reunited into a trunk below the tumour.

It is interesting to observe how closely this case resembled that related by Cheselden, in which, we learn from Wood, was the first ever recorded of neuroma.

Cheselden says:—"A tumour forms in the centre of the cubital nerve, a little above the bend of the elbow; it was of the cystic kind, but contained a transparent jelly. The filaments of the nerve were divided, and ran over the surface; the tumour occasioned a great numbness in all the parts that the nerve led to, and excessive pain on the least touch or motion. The removal of the tumour was effected, and the account of the case, a few weeks after the operation, was:—The pain has entirely ceased, the numbness a little increased, and the limb is not as yet wasted."—*Cheselden's Anatomy.*

2nd Case.—In most cases where the neuroma is solitary, and situated in the course of a nerve where it is exposed to injury or pressure, such as that even of the ordinary dress, the pain excited in it by the most trivial causes is intolerable to the patient, who becomes anxious to undergo any operation to be relieved of the disease. Such was the case of a patient, under the care of the late Mr. Mucedowel, in the Richmond Hospital.

He had a neuroma about the size of a Spanish nut, in the course of the posterior tibial nerve, where it passed behind the inner ankle. Such were the pains endured by the patient in his daily work, as a labourer, that he could not earn his bread. At a consultation, at which I also attended, it was advised that the neuroma should be cut out, dividing the nerve across, both above and below the tumour, which was accordingly done. The tumour removed in this case was of a fibro-cellular structure, surrounded by a dense covering. The operation was completely successful in relieving the man of his suffering, and the motions of the foot were not materially impaired by the effects of the complete division across of the posterior tibial nerve. Although this case occurred many years ago, and was quoted from memory, it is well remembered by Dr. Hutton, Dr. Smith, and by the narrator himself.

The last case is that of a woman, C. Mulvany, aged twenty-seven, a widow, mother of four children. About two years ago she had the misfortune to fall against a window, from the broken glass of which she received a transverse wound of the forearm, about an inch above the wrist-joint. The wound divided some of the tendons across, as well as the median nerve, and it was five or six months before the wound was perfectly cicatrized. Subsequently to this a tumour formed in the course of the median nerve, just underneath the central part of the transverse cicatrix. This tumour, when she presented herself at the Richmond Hospital in September last, was about the size of a large almond; it was hard to the touch, and was the source to her, to use her own language, of "awful suffering," and completely prevented her supporting herself or family. When at her work, if anything, even her dress, accidentally touched the tumour, severe pains shot down to the hollow of the palm of the hand, and upwards to her shoulder; she also complained much of numbness and coldness of all the parts of the hand supplied by the median nerve. As in the case of Nolan, who had neuroma in the ulnar nerve, the little finger and ulnar side of the ring-finger were the seat of the peculiar sensations extending down from the neuromatous swellings, so in this case the peculiar sensations were felt principally in the parts supplied by the median nerve. Hence she complained that there were always coldness and numbness of the radial side of the ring-finger, and of the thumb and sides of the other fingers, always excepting the ulnar side of the ring-finger and both sides of the little finger. The parts supplied by the ulnar nerve were in this case in their natural state as to temperature and feeling, and no pains radiated along the course of the branches of any nerve but those of the median. In this case a neuroma about the size of an almond, originating in a cicatrix formed across the partially or completely divided median nerve (well represented in the cast presented to the society), was the source of all her suffering. The obvious treatment for her case was to cut out the neuroma, and to effect this, involved the necessity of completely cutting across and removing a portion of the median nerve with the neuroma. Experience, however, led me and my colleagues to advise her to have the operation at once performed, to which she very gladly assented, as she found her sufferings daily become aggravated, and all she had tried utterly useless. On Wednesday, the 9th of September, I removed the neuroma, in presence of the Richmond Hospital class.

Operation.—An incision one inch long was made over the tumour, in the direction of the longitudinal axis of the forearm. The fascia was thus exposed, and a director passed underneath it, and the membrane divided on it. The upper extremity of the tumour was soon arrived at, and the point of entrance into it of the median nerve discovered; a

probe passed under the trunk of the median nerve, and this last cut across. A hook was next passed firmly into the tumour, and the surrounding part dissected from it, until the lowest extremity of the tumour was reached; and the median nerve, where it made its exit from the lowest part of the neuroma, was cut across, one inch of it, including the tumour, having been completely removed. The operation, as may well be conceived, caused very great pain to the patient; the result, however, has been most satisfactory, the wound having healed in the course of a week. Her statement at the hospital, a few mornings ago, was, that there still remains some sensation of coldness and numbness in all those parts supplied by the extreme branches of the median nerve. But it was learned that there is now no morbid sensibility in the seat of the cicatrix where the neuroma existed; no shooting or stinging pain darting down to the palm or upwards. In short, with great joy, she states she is enabled to earn her bread, and (though with great difficulty in these times) to support her children by her labour.

Dissection.—On examining the portion of median nerve removed, which, including the neuroma, was about one inch and a quarter in length, it was noticed that the nerve, as to colour, consistency, and structure, seemed above and below the tumour, to be quite normal. The oblong tumour itself had spread over it here and there some slender fibrillæ of the radial nerve; a longitudinal section of it presented a hard, white, homogeneous mass of the same consistence throughout, having no distinct cyst, but with an appearance as if the neurilemma of the nerve had been continued over it.

In this case the surgeon had no choice between the operations that might have been proposed, viz., either that of cutting out the portion of the median nerve, including the neuroma; or that of dissecting out the tumour from the surrounding branches of this nerve as they passed outside or through the neuroma. The circumstance of the disease in this case having originated from a wound, which had penetrated deep into the centre of the median nerve, showed that there was no other alternative than that of cutting completely across the nerve. We learn, however, that on the Continent there have been cases of large neuromatous tumours connected with great nerves, such as the sciatic, which tumours have been safely disengaged from the lash of branches or fibrillæ of which this real nerve is made up. Velpeau mentioned in his clinical lectures, that he had successfully treated a remarkable case of neuroma of the sciatic nerve in this way; and he states that Chelius, of Heidelberg, had similar success. In these cases the tumours were purely neuromatous.

QUININE IN INTERMITTENTS.

A paper by Dr. Holmes has been published, in the *American Journal of Medical Sciences*, of considerable interest, on the use of quinine in the malarious diseases of hot climates, drawn from his experience as an army surgeon, stationed at an unhealthy post in Florida, of which we now present our readers with an abstract. The diseases of this country are said by the author invariably to assume an intermittent or remittent form. The experience of physicians in the warmer climates of Europe shows that larger doses of quinine are necessary to check fevers, than in regions where malarious influence is less predominant.

Starting with the principle deduced from his experience in Florida, that "in proportion to the amount of miasmata in the system, as shown by its effects, so must the dose of quinine, for the cure, be increased or diminished," he proceeds to state the mode in which he was in the habit of administering it with the greatest effect.

Dr. Holmes never gives quinine in a torpid or gorged state of the bowels, believing, very rationally, that under such circumstances the effect will be comparatively lost. For this reason he precedes the administration of quinine by an active cathartic, if necessary. He has given it when the

bowels were actively purged and irritated, without increase of the irritation.

Much discussion has recently occurred as to the most advantageous mode of administering quinine: some practitioners adhering to the common practice of giving it in small and divided doses, while others advocate very large doses at longer intervals. Dr. Holmes belongs to the latter class, and speaks most enthusiastically of this mode of administration.

It must be borne in mind that the malarious diseases of England and other countries of the temperate zone bear about the same proportion in severity to those of hot climates that ordinary diarrhoea does to Asiatic cholera. An English ague seldom causes the death of the patient until after repeated paroxysms, and is comparatively under the control of small doses of quinine or arsenic; on the other hand, the agues of India and the hotter regions of America may cause death by the first paroxysm, and very frequently the patient does not survive the third. Now, in such a state of things, it is absolutely necessary that the disease should be cut short at once in order to save the patient; and here small repeated doses of quinine, requiring time for their action, are inadmissible.

At the outset of the paper, the author states that the largest single dose of quinine he has administered was eighty grains; but the ordinary dose recommended by him is fifteen grains dissolved in water by the aid of a little vinegar. Suppose this to be given in the afternoon, at three P.M., the patient having had an attack of intermittent on the same day, commencing at nine A.M. and terminating at two P.M. The fever, being a quotidian, will return the succeeding day at the same time, despite the quinine; the chill and fever will be of a lighter grade, but will be as distinctly marked, and will remain as long; but the third day the patient will be entirely free from the disease, and will not experience, during any part of the day, the slightest symptoms of it. In treating many hundred cases of fever in Florida, the author has not met with more than twenty exceptions to this rule. If the bowels are in good condition, the quinine is given at once; if loose, in combination with twenty drops of laudanum. In some cases, even this dose of quinine has not proved sufficient; but the cause of its failure could not be determined.

He thinks that in those cases where a return of the paroxysm takes place, this occurs most frequently on the seventh day, then on the fourteenth and twenty-first. In these cases the same dose of quinine is administered shortly after the paroxysm, and the disease is again cut short. When quinine is given in anticipation of the attack on the seventh day, the fever is very apt to change its type and return on the eleventh; and hence he draws the inference that quinine should not be given in anticipation of an attack on a critical day.

Having mentioned some cases of periodical disease, complicated with inflammation, in which the patient was first treated with quinine for the removal of the ague, and the inflammation subsequently removed by antiphlogistic measures, he says—"Every intermittent disease is to be checked immediately. Quinine, as a remedy for periodicity, is to be given regardless of any existing state of inflammation. Never give quinine in divided doses, when directed for the immediate cure of periodical disease. To be certain of the operation of quinine, in a constitution with which you are not acquainted, it must be given eighteen hours before the desired result. In emergent cases it may be given in the lowest state of prostration, or the highest grade of fever. As a general rule, fifteen or twenty grains will be necessary for an intermittent, and thirty to fifty for a congestive, fever. Never give quinine for the cure of a periodical disease, in anticipation, when the periodicity exceeds five days."

Small continued doses harass and irritate. A patient who has taken sixty or more grains of quinine in the course of a month, in small doses, is indignant at the idea of a fifty or sixty grain dose being given in Florida, which suffices for the same period. This is illustrated by reference to calomel, of which a very large quantity may be taken at one time with no bad effect, whereas the same

quantity in divided doses would produce irritation, fever, and pyralism.

Extracts from the hospital books of the station in Florida are adduced as proofs that comparatively small quantities of quinine were given by him in lengthened periods, although the doses were large. The largest quantity mentioned is 220 grains, in six months and seven days—by no means a large amount.

His reasons for the large doses given in Florida are sufficient. In the diseases of that climate, eminently periodic in their character and of a highly dangerous type, it is apparent that the plan of giving quinine in divided doses cannot be entertained. The disease is one in which so much time cannot be lost. The immediate effects of large doses are thus described. The patient feels a buzzing and murmuring in the ears, a partial deafness, which often continues for twenty-four hours; a great sense of fullness about the head, and after, a dull pain across the forehead; there is generally more or less excitement or partial delirium, without excitement of the spirits in any degree. Dr. Holmes has often seen patients under the effects of quinine wander and talk incoherently, as if from the influence of alcohol. Occasionally it will produce a pricking sensation in the skin, and a quivering in the muscles of the fingers and eyeballs. One patient he knew who was always made perfectly insane, so that he had to be confined; and this even by the administration of five grains of quinine. He never saw any of these symptoms last much longer than twenty-four hours.

"Enlargement of the liver and spleen have," says the author, "been attributed to large doses of quinine as well as subacute inflammation of the alimentary canal, dropsy, and palpitation of the heart." These are really effects of miasmatic fevers, and were well known long before quinine was discovered. Chronic affections of the liver and spleen

are incident to hot and malarious climates without disease even as a cause. He believes them to be often the pure result of malaria. Enlarged spleens are quite common, chiefly with those who have suffered from intermittents, but sometimes in persons who have never been sick, though living in a malarious district.

One circumstance has attracted the author's attention in cases of disease from miasmatic origin in Florida—the abnormal action of the heart: its beats, if the patient has been weakened by disease, are so tumultuous and diversified, but without afford so little sign of organic lesion, that, if not acquainted with the former condition, the prognosis will be most unfavourable. He has seen but few permanently bad results from this cause.

The following description of the condition of a person even in "good health," in a miasmatic region, is interesting, as showing the inferior degrees of influence of this subtle agent:—"His rest will be broken at night; his appetite will not be so good as formerly; he will not enjoy that feeling of full health he has been accustomed to; his system will be attacked from time to time by the offshoots of the disease preying on others around him, though he will not be sick, and may escape with a like freedom from disease during all his sojourn in the country; but the whole constitution seems in some degree to labour under the influence of malaria; slight wounds that would elsewhere heal in a few days' time must here undergo the slow process of suppuration and granulation, and even this does not come on early, the wound remaining some days without any visible advance towards a cure. You cannot persuade a slight incision of the skin to heal by adhesive inflammation; and I have repeatedly seen wounds, in habits that were to all intents healthy, assume the deep burrowing condition."

STATISTICAL ACCOUNT OF THE ACCIDENTS BROUGHT TO THE LONDON HOSPITAL.

London Hospital, Jan. 8.

SOME OBSERVATIONS ON MR. SYME'S LAST PAPER ON POPLITEAL ANEURISM, IN THE MONTHLY JOURNAL.

Mr. Syme's communication opens with the narration of a case of popliteal aneurism successfully treated by the Hunterian operation. The ligature separating on the 36th, and the patient allowed to leave the hospital on the 39th, day. We are then told that this is the "sixteenth" time Mr. Syme has tied the femoral artery without experiencing any bad effects from the operation; and he goes on to state that "the public opinion" of the profession having re-

proached him for continuing a practice replete with danger, however fortunate his results have hitherto been, he has considered it to be his duty "to make a careful inquiry into the present state of the question." How far the professor has succeeded in arriving at the truth of the question, I shall leave those who may read these remarks to determine. Mr. Syme and Mr. Busk (surgeon to the Dreadnought Hospital Ship) having applied a ligature to the femoral artery twenty-five times, without death having ensued in a single example from the operation, Mr. Syme assumes from this fact, and from this alone, "that the operation is nearly, if not entirely, free

from danger." As well might Cheselden, Martin, and other successful lithotomists, assert that the operation of lithotomy is one unattended with danger, because they had had a succession of fortunate cases. The professor of surgery, being gifted with second sight, years ago predicted that "ulcerations, sloughs, and even fatal results, would not be wanting;" and, marvellous to relate, a portion of his prophecy has come to pass. Slight ulcerations, possibly sloughs (when pressure has been improperly used), have occurred; but Mr. Syme has failed, by the *unsuccessful* (?) cases he has quoted, to prove that death has resulted from the *treatment by compression*. Let us examine the cases (three in number) brought forward to support Mr. Syme's argument. The first patient, under the care of Dr. Bellingham, dies from erysipelas (prevalent at that time) attacking the diseased limb. Is it fair to assume that such a result was caused by pressure, however improperly applied; and how much more probable is it that such a result would have ensued from a wound of such an extent as that required in the application of a ligature to the femoral artery, involving, more or less, every structure composing the limb, the bone and its immediate investment excepted? Although Mr. Syme may have tied the femoral artery successfully under circumstances "so unpromising" (hospital sore and erysipelas prevailing) that no surgeon of the least prudence, except from urgent necessity, would perform the operation, can such a statement be admitted as an argument against the employment of compression, because, on the other hand, a patient has died from erysipelas excited by a slight abrasion of the cuticle on the thigh? Let me ask Mr. Syme whether the case just quoted is sufficiently "unpromising" for him to have recommended the application of a ligature to the femoral, a patient, from Dr. Busk's account, labouring under "anasarca, anæmia, enlargement of the liver, and valvular disease? Again, the second case, one occurring in the practice of Mr. Busk, is one of gangrene supervening upon complete obstruction of the artery, proves too much for Mr. Syme. The history of the case is briefly as follows:—J. B. comes under the care of Mr. Busk for popliteal aneurism of ten days' duration, accompanied with effusion into the knee-joint. Pressure is applied in the usual manner; the knee-joint (previously full of fluid) becomes red, swollen, and tender, and the patient dies from gangrene commencing in the limb as soon as the circulation through the popliteal artery ceased. An examination being made of the limb after amputation, it was found that the disease was cured, but that the cavity of the joint had been perforated by the pressure of the aneurismal tumour, and that an abscess had formed external to the sac. Mr. Busk naively remarks, "It is of course impossible to say that under these circumstances the operation would have been attended with a more happy result, although I am inclined to believe that it would in a great degree have been prevented, by an earlier dispersion of the aneurism."

If we are to deal with assumptions, I for one do not wish to enter the lists with such speculative minds as Mr. Busk. It is, however, but fair to the treatment by compression to observe, that there are two facts against his hypothesis—the one being, that the knee joint was seriously affected previously to any treatment; the other, that the rapid dispersion Mr. Busk writes of would, most probably, not take place in fourteen days—the duration of treatment in this case. Gangrene caused this patient's death, probably accelerated by the swelling about the knee obstructing the collateral circulation; but to say that such a result would have been avoided by the Hunterian operation is more than any surgeon is justified in asserting. Let me ask Mr. Syme, if he had known the condition of the parts *before*, whether he would have recommended *any* performed his favourite operation?

The third, a case well-known to those interested in the subject, occurred in the practice of Mr. Cusack; the patient clearly died of heart disease

(of which there was abundant evidence before the treatment was commenced) forty-eight hours after the popliteal artery had become impervious. It was an unfortunate coincidence; but where is the argument against pressure?—and who can say that the cure of the local disease caused the death of this man?—why did the heart allow forty-eight hours to elapse before it ceased to perform its functions?

The next remark Professor Syme makes betrays very gross or very wilful ignorance; he says—"Indeed there seems to be some peculiarity in the Dublin reports on this subject, since, with regard to another case, it is said, 'that after recovery the popliteal artery of the affected limb pulsated as strongly as that of the sound one'; which is plainly quite impossible, if there really had been an aneurism." This is not only possible, but probable, and a pathological fact which I should have supposed it impossible for a professor of surgery to be ignorant of. In the spontaneous cure of an aneurism, the sac may become filled up by coagula, and the canal of the artery remain pervious—a fact observed long ago by Hodgson, who records a case where so small an artery as the anterior cerebral remained pervious, although an aneurismal sac, in connection with it, had undergone a spontaneous cure. The cure effected by nature, and compression *when properly applied*, intimately resemble one another; and I can see no reason why the popliteal artery should not remain pervious, although the aneurismal sac is closed by fibrinous deposits. Mr. Syme, with great confidence, asserts that the operation is rendered much more difficult by the previous application of pressure. From the successful results that have attended upon the treatment by compression, few opportunities have been given to *deft* operators, like Mr. Syme, to test their anatomical and manipulative acquirements. There are, however, enough to show that it offers no valid objection to the practice, and that no difficulties of any importance have as yet occurred in the published cases.

If Mr. Syme is founding his remarks upon the unpublished cases he alludes to, it is his duty to communicate the facts of those cases to the profession, or to reserve his opinion until the surgeons to whom they have occurred imitate the example of Mr. Busk.

Mr. Syme writes of the ease, rapidity, and safety with which the operation may be performed, and gives some commonplace rules for the observance of the operator. If my memory serves me rightly, Mr. Syme's operations are not always unattended with what, to bystanders, appears to be danger. Not long ago, I remember hearing, and, I think, reading, of gushes of blood that followed the introduction of the aneurism needle beneath the artery: Mr. Syme, however, pulled the ligature tight, and ultimately all went on well. Dr. Bellingham's table, containing twenty-three successful cases, is next alluded to; and Mr. Syme finds that the average duration of compression in each of those cases is thirty-eight days, which he describes as—"thirty-eight days and nights of misery to escape a few minutes of trivial uneasiness"! The whole merits of the question appear to me to rest on the just estimate of this passage.

Felicitous as Mr. Syme is in his description of the operation for popliteal aneurism, and although even the objection (through the labours of our transatlantic brethren) "of a few minutes of trivial uneasiness" is now removed, I venture to assert that the merits of the practice are not thus disposed of. It is true that thirty-eight days were occupied as an average of the treatment; but I would remind Mr. Syme that the surgeons did not, for thirty-six days, look with anxiety to the separation of the ligature, nor had they the same fears of gangrene that every rational man must look forward to when the circulation through the principal channel of a limb has been *suddenly* cut off.

Mr. Syme next sneers at those who he imagines are unable to apply a ligature to the femoral artery, because they employ compression;

and he then attempts to make a comparison between the treatment of aneurism by compression, or ligature, and the treatment of retention of urine by the catheter or trocar. An analogy cannot be said to exist, and I need hardly observe, that when this practice receives the cordial support of two of his own countrymen, so eminently distinguished as operating surgeons as Messrs. Liston and Ferguson are, and when the very table Mr. Syme quotes contains such names as Cusack, Hutton, Liston, Porter, Harrison, and Bellingham, amongst the surgeons to whose practice Mr. Syme alludes, I need not attempt to prove that these are not the men, to use the professor's own words, "who feel it necessary to choose inferior means" in the treatment of surgical disease. "Let every man act according to his powers," says Mr. Syme; but I would beg to remind him, that that tribunal to which both great and small must submit—the public opinion of the profession—will judge of a man's powers by his acts; and I fear that, when they deliver their verdict upon Professor Syme's recent literary labours (*vide* observations on lithotomy, amputation in the thigh, and upon "dear Liston's" case of traumatic aneurism, and now upon popliteal aneurism), it will not be in favour either of Mr. Syme's good sense or his liberal appreciation of the labours of his contemporaries. Your obedient servant, C. J.

Feb. 12.

ON A SINGLE AND DOUBLE CELL ETHER INHALER.

By A. SMEE, F.R.S., Surgeon to the Royal General Dispensary, and Lecturer on Surgery.

I have already called the attention of the profession to three forms of ether inhalers, which I am informed are in constant use. To distinguish them I should recommend them to be called the pipe inhaler, the inverted pipe inhaler, and the hot water ether inhaler.

In spite of all my entreaties, I cannot persuade the manufacturers to make the air ways and valves half large enough for my fancy; and I therefore beg that this point may be particularly regarded, before the instruments are purchased. Of the three former ones described, I give a decided preference to the last, next to the second, and I conceive that the pipe inhaler may be altogether abandoned.

The valves should also play in all positions of the instrument, and for that reason I prefer the flat-door valves—which, also, allow the respirations of the patient to be observed by the surgeon.

These forms of inhalers, I believe, however, will be superseded by the single and double cell ether inhalers, which I am now about to describe. These single-cell inhalers, consist of a box, crescent shaped, and made of silver, silver gilt, soft metal, tin, copper, electro-plated, glass, or other materials; in fact, a nipple-glass will do for a glass single-cell apparatus. The front surface is pierced with holes for respiration, and, when in use, a piece of sponge saturated with ether is placed in the box, and the whole is ready for use. By this contrivance, valves, flexible tubes, and all other cumbrous appendages are abandoned, and respiration is freely accomplished.

The double-cell apparatus merely differs from the single-cell, by having a narrow chamber between the sponge, and another to prevent any fluid ether, by any chance, reaching the mouth. In both cases, a little pad may, or may not, be employed, at the will of the operator.

The double-cell apparatus may have a valve at the intervening chamber for expiration, but I do not think it necessary. Experience alone can decide whether it will answer for all cases, though I have ascertained its great superiority in many instances. This, together with the hot water ether inhaler, will be found to answer in all cases, and produce far more rapid effects than other inhalers employed. These inhalers are neither patented nor registered; and Ferguson, Horne, Jones, and Maw are conversant with the manufacture.

Finsbury-circus, Feb. 9.

ON THE EFFECT OF ETHER.

By W. PHILIPOT BROOKER, M.D., M.R.C.S. England, Surgeon to the General Hospital and Dispensary, Cheltenham.

Since reporting my former case, I have successfully performed the following operations under its effect:—

Ann Weston, aged sixty-nine, living at No. 1, Burton-street, had been suffering for the last twelve months with fistula *in ano*, and had been during the whole of the time confined to her bed. She was of a very nervous, debilitated habit, and would not give her consent to the performance of an operation; but, upon hearing of my former painless case, she sent for me and desired to have the operation performed. On examination, I found the whole verge of the anus in a state of ulceration, accompanied with great pain; the probe discovered a fistulous sore extending full four inches into the rectum, the walls of it of some thickness. Having put her in train for performing the operation, it was done in two days afterwards. The patient was laid on her back, with the head elevated (so as to have no difficulty with the ether), the buttocks raised, knees drawn up and held apart; I then passed up my finger and inserted the director, when the inhalation of the ether commenced (with merely a bladder and elastic tube), and she was in a complete state of unconsciousness in two minutes; the bistoury was then introduced, and the fistula divided in its whole length, without her showing the slightest symptom of pain or uneasiness. When it was over, I asked her—"If she had quite made up her mind to have it performed?"—she said "Yes, please, go on with it as quickly as possible." When told it was over, she expressed great surprise. At this operation the following gentlemen were present:—Drs. Wright, Bagnall, Bull, Smith; Messrs. Eve, Orrell, Peach, Alex, Tibbs, Rowe, Norman, Churchie: and all expressed themselves satisfied with the result.

The next case was that of Ruth Monk, aged twenty-one, who wished to have the last molar tooth extracted, under the ethereal influence. She is of a full plethoric and excitable habit; in one minute and a half she was in a state of unconsciousness, from the ether, and became quite unmanageable; her face flushed, and she required two persons to hold her. I lanced the gum without any sign of pain, and she recovered her sensibility immediately, as she was very anxious to have her tooth extracted. She again inhaled it, and when under its influence some excitement returned, and on drawing the tooth with the claw, she cried out, "Oh!" but, on coming to herself, stated she had had no pain, and, having had out nine teeth before, she could judge of its effect, and said, "I will never lose another tooth except I am prepared in a similar manner so as to give no pain."

Feb. 1.—The following cases were operated on to-day, in the presence of fifteen gentlemen, most of them members of the profession:—

John Coombes, aged fifty-six, a labourer on the roads, residing at Charlton, of a strong plethoric habit of body. Whilst at work he met with an accident (three weeks back) to the middle finger of the right hand; mortification took place, and the first joint sloughed away; still he would not consent to the loss of the finger, and the disease extended to the metacarpal bone. Having heard he could have it taken off without suffering any pain, he applied this morning to have the operation performed. The ether was inhaled, and the man under its effects in six minutes; he remained so for five more. The finger was taken off by a V-shaped incision, opening the metacarpal bone half way down, with Liston's bone-nippers. The patient did not show the slightest sign of pain, and stated he heard the bone cut, but positively asserted he felt no uneasiness of any kind, and grumbled much at the suffering we gave him when taking up the arteries afterwards. I allowed this case to remain for half an hour before I dressed it, as I am inclined to think secondary hemorrhage will

often occur after the effect of the ether has passed away; reaction does not until then become perfectly established; small arteries often escape untied if we dress it immediately, and union will not take place so well on account of extravasation of blood. The pulse in this case was, before the operation, 84, and during the ethereal process it varied from 60 to 70.

William Guy, aged twenty-one, residing at 44, Duke-street, of a pale, exsanguineous habit of body. Has had phymosis from syphilis for several months, and, wishing to have the glans penis liberated, submitted to the operation. (The ether was inhaled, and produced its effects in three minutes). This was performed by dividing the skin down to the end of the gland, without any sign of pain, and he states he did not feel anything of it. Pulse, when in the ethereal state, was 75, and soft, and before that time, 90.

A servant, aged thirty, had four stumps extracted, without giving her the slightest pain, by Mr. J. Tibbs, surgeon-dentist, of this town. The ether was inhaled from a modification of Dr. Snow's apparatus, and she was put under its influence in less than two minutes, and remained so nearly five; and positively states she felt nothing.

Lot Organ, aged thirty-six, residing in Grove-street, of a spare habit of body, has had a disease of the left elbow-joint for the last year or two, and would not consent to its being amputated before; but, the general health becoming injured, he now consented. The ether was given with Dr. Snow's apparatus, and after its inhalation during four minutes he appeared quite unconscious. The circular incision was made through the skin, and he cried out most lustily, and continued doing so through the whole stage of the operation. After it was all over, he stated "he felt the first cut and also the bone sawed, but he was in a dream and smoking a pipe, which some one tried to take from him."

I can only view this case as a failure; and I think it right alike to report all, whether failures or not. The other cases were decidedly satisfactory. I may state that, in the above operation, the mouthpiece did not fit nicely to the mouth, and he appeared to have inhaled fresh air by its side.

Albion-house, Cheltenham, Feb., 1847.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF SCIENCES.

Meeting of Feb. 15; M. BRONNIER in the Chair.

ELECTION OF A MEMBER.—A seat having become vacant by the demise of Colonel Bory de St. Vincent, a ballot took place for the election of a new member of the Institute. M. Civiale was the fortunate candidate: he obtained thirty-six votes (fifty-six members present), and was therefore declared to be duly elected.

INHALATION OF ETHER.—The discussion of this important subject continued this day to occupy the attention of the academy; but no new or interesting facts were elicited. The debate which had acquired a personal turn, chiefly referred to the nature of the accidents experienced by a patient of M. Velpeau.—The meeting adjourned at half-past five.

ACADEMY OF MEDICINE.

Meeting of Feb. 16; M. BEGIN in the Chair. INHALATION OF ETHER—DEATH—POST-MORTEM EXAMINATION.

M. Jobert remarked that in two cases death after operation had occurred in his wards, and that the inhalation practised in both instances did not appear to him to have been altogether unconnected with the fatal issue. The first case was that of a woman, who breathed the ethereal vapour during thirteen minutes; insensibility was not completely produced, and the operation was attended with considerable pain: heat of the head,

and pain in the trachea and bronchi, were afterwards complained of; erysipelas appeared, and the patient died suffering from violent bronchitis and badly-defined nervous symptoms. The post-mortem examination had, unfortunately, been very incomplete, the deceased's friends having objected to dissection of the brain or spinal chord; but the trachea was found red, and the heart gorged with blood.

M. Jobert had since then the misfortune of losing a second patient, who had suffered amputation of the thigh in consequence of white swelling of the knee. Inhalation of ether had, after four minutes, brought on complete unconsciousness; the operation was painless, and it was only two hours later that the patient recovered her senses. The following day the ideas were incoherent, and articulation of words difficult; headache was present, and a violent cough, which lasted seven days. On the ninth day, violent neuralgic pains were observed in the face, and contraction of the sterno-mastoideus muscle, and also of the abdominal walls. On the fifteenth day the patient died, and the body was examined with the greatest care. The small blood-vessels of the pia mater, of the brain, and spinal chord, were in a state of congestion, and the cerebral substance, also, overloaded with blood. At the union of the cervical with the dorsal region of the chord, was noticed a red softening, by which the symptoms observed during life were fully accounted for. The ventricular cavities of the brain were filled with serum, the mucous membrane of the pharynx was of an intensely red colour, and the basis of the tongue denuded of its epithelium; some pus was also found in the pharynx. The œsophagus was much congested; the pulmonary artery was red on its internal aspect; the heart had somewhat lost its consistency. The first patient was thirty years of age, the second over forty. M. Jobert proceeded to say, that in this second case it appeared evident to him that the inhalation of ether had a good deal to do with the symptoms observed: he was of opinion that it had caused congestion of the nervous centres and irritation of the mucous membranes, and that these cases showed with what caution the new method should be used. He had observed during operation that the arterial blood lost in some degrees its florid aspect, but he had not seen this effect so well marked as M. Amussat had stated. Several of the learned surgeon's patients had been seized with universal tetanic contractions of the muscular system, which had rendered it necessary to give up the inhalation.

M. Renaud, director of the Veterinary School at Alfort, stated that in the experiments instituted on animals at that establishment the dark colour of the arterial blood had not been observed; but the serum exhaled a strong odour of ether, and, in all cases, dry ecchymotic patches had been met with under the pleura: no anatomical change whatever had been detected in any other texture.

M. Amussat remarked that the differences in the results of observation mainly depended upon the method of conducting the experiments. If, at the beginning of the operation, an artery and a vein were simultaneously uncovered, the artery was observed to acquire gradually a darker colour, so as not to be distinguishable, except by its pulsations, from the vein, when complete unconsciousness was established.

Professor Piorry gave an account of the results of inhalation of ether in four cases of neuralgia. Pain had been suspended in a temporary manner, but violent hysterical attacks had been produced.—Meeting adjourned at five o'clock.

FACULTY OF MEDICINE.

LECTURES ON GENERAL PATHOLOGY, BY PROFESSOR ANDRAL.

Looking further into the subject we have begun in our last lectures, viz., Sympathy, we find that when the irritation of any one organ causes the appearance of sympathetic symptoms, these may chiefly arise from some part which

previously was the seat of disease. The contrary is sometimes observed, a new irritation of any viscous causing a temporary cessation of morbid symptoms in another, *e. g.*, the frequent arrest of phthisis pulmonalis during gestation; it may also happen that an adjuvant irritation, which had disappeared, recurs when a fresh irritation invades another part of the system. In acute disease sympathies are more numerous than in chronic affections. We may also notice that a singular diversity exists between the different viscera with regard to their liability to become the seat or the origin of sympathetic symptoms. Thus the brain and the stomach very readily occasion sympathetic suffering in other parts, and also take a notable share in the maladies of distant viscera; serous membranes, on the other hand, are often the occasion, but seldom the seat, of sympathetic symptoms; lastly, the heart is much oftener the seat than the occasion of sympathy.

Sympathetic phenomena may be studied in the various tissues, or in the organs formed by the assemblage of these tissues: the latter investigation being far more important than the former to the pathologist. The influence of climate and temperature on sympathies must be carefully noticed; in warm countries they are more numerous, and more easily developed, than in temperate or cold latitudes; hence the peculiar physiology of many diseases of tropical climates, where the brain and liver frequently testify the part they take in the irritation of the other viscera: the former by giving to inflammatory affections an ataxic form; the latter by the ready production of hepatic alterations under the influence of intestinal suffering.

The sympathetic phenomena, of which we have endeavoured to lay before you a short history, are vital manifestations which do not admit of any one of the numerous explanations which have been brought forward. Community of structure or of function, the distribution into different parts of nerves emanating from one source, nervous anastomosis, are each and all theoretical explanations of sympathy, which account for a certain number of phenomena, but which do not apply to all. We know no more of the intimate nature of sympathy than that of the electric fluid, the existence of which is proved to us only by its effects.

DIMINUTION OF IRRITABILITY.

This diminution is betrayed to the observer by a decrease in the activity of vital phenomena, and produces a condition which has been termed *asthenic* or *hyposthenic*, in contradistinction with the *hypersthenic* state—a division introduced by the Italian school, represented chiefly by Rasori and Cominasini. The *asthenic* state may be congenital or acquired, and may be in itself the only morbid condition appreciable, or coincide, on the contrary, with numerous diseases. It may exist in disease as an element of variable nature—as a cause, as an effect, as a symptom, or a complication. We find that it acts as a cause in consumption, and in many chronic affections; it is an effect or result in the tedious convalescence which follows protracted illness; it is a simple morbid element in typhoid fever, and it is often an important complication which changes the aspect of the symptoms, and modifies the treatment.

If the hyposthenic condition be congenital, its cause is not to be sought for in the composition of the blood, or in the state of the nervous system: for both the nerves and the circulating fluid have been changed originally by the *nixus* formations which presided at the formation of the being; their alteration is an effect, not a cause. Acquired *asthenia* recognises numerous producing causes—some of which are external, others inherent, to the organism. Amongst the first we may place the influence of moisture, particularly combined with heat: extreme heat depresses the system by causing abundant perspiration, and it is well known to all those who have practised medicine in tropical climates that antiphlogistic measures must there be used more sparingly than in our more temperate lati-

tudes. The weakening influence of warm baths is a fact very generally admitted. Vitiated air, by the presence of miasmata, or by the respiration of many persons, also exerts a very debilitating action. The influence of bad or insufficient food on large populations is admitted to promote the development of fevers of a putrid character. The excessive indulgence in watery drinks must also be carefully guarded against; and we may say that British practitioners have been perfectly correct in depreciating the continual and exaggerated exhibition of *tisanes*, to which French physicians have been so much and so long addicted. Medicines, poisons, often act as useful or injurious agents in depressing the general or local irritability: it is thus that digitalis acts upon the heart. The undoubted action of a certain class of medicines, called counter-stimulants, is to diminish irritability: under their influence a remarkable languor is established; the heat of the body seems to diminish (we say *seems*, because thermometric proof of the fact has never been brought forward), the arterial pulsations lose their strength and frequency; a tendency to syncope, attended with nausea and vomiting, is sometimes produced; vertigo, and also some irregular nervous symptoms. When counter-stimulant medicines are exhibited to a healthy subject, the above train of symptoms is met with; but it is not so in disease, when, the irritability of the system having been carried more or less beyond its healthy standard, hyposthenic accidents are produced by the exhibition of these drugs, only when irritability has first been by them brought down to its physiological level.

Diminution of the globules of the blood, and excessive excitement of the nervous system, are the principal proximate causes of diminution of excitability. The *asthenic* condition thus induced may be general, or confined to one organ. When *asthenia* is physiological, the functions are languid, and require for their accomplishment the exhibition of hygienic or pharmaceutical stimulants: venesection readily occasions palpitations of the heart and dyspepsia, and most diseases acquire a tendency to pass into chronic sufferings, or to assume an *adynamic* form. This general debility may in itself constitute a morbid entity, in consequence of which the functions become more or less impaired, and the digestion difficult, particularly that of non-stimulating food. In this state, aqueous drinks are not usually well tolerated by the digestive organs, and frequently occasion obstinate vomiting. The pulse loses its regularity, and syncope is easily produced; with regard to its frequency, it is not uncommon to find it increased—a circumstance usually noticed in cases of abundant hemorrhage and of advanced chlorosis. Capillary congestion is also the possible result of debility—a fact we have not long since established in these lectures. Dyspnea also shows itself; and the various secretions, particularly perspiration and urine, are increased in quantity, and more watery in their nature. Various disturbances of innervation are likewise observed; by prolonged abstinence, loss of vision has been produced, and also paralysis of motion of the lower extremities in cases of nervous disease of the stomach, in which the patient had been for some time deprived of food. We may here notice that we have often been struck with the absence of any anatomical change in the spinal chord, in persons who had died from the progress of paraplegia resulting from debilitating causes. Perversions of excitability are also noticed, such as delirium, hallucinations, and convulsions. *Asthenia* may, lastly, show itself in the form of a complication of existing disease, and give a special character to the general aspect of the malady.

SENSIBILITY.

This property of living textures manifests its existence only where organized matter is arranged in a peculiar form, and requires for its production a particular apparatus, *viz.*, the *nervous system*. The numerous causes which increase, diminish, or destroy sensibility are very much the same as those which exercise an analogous

influence over the vital property previously alluded to. Some special agents tried, however, to diminish it: for instance, the drugs called narcotic. Disease modifies sensibility by increasing or diminishing its intensity, or by abolishing it altogether.

Increase of sensibility bears the name of *hyperesthesia*, and may either show itself by augmentation of sensibility in any part, or by producing in organs which naturally do not convey their impressions to the sensorium, the property of so doing when in a diseased state. Sometimes this production of sensibility is preceded by congestive or inflammatory appearances; sometimes, on the contrary, as in neuralgia, nothing of the sort is observed. A natural or acquired neurosthenic condition of the system, considerable mental exertion, &c., favour the development of abnormal sensibility. Often, under the influence of these causes, the stomach becomes the seat of excessive pains and of other troublesome functional symptoms; it is in such cases that cold ablutions have been found of material service by their invigorating influence on the nervous system. After abundant hemorrhage, prolonged abstinence, or chronic disease in different parts of the body, pains are frequently experienced, which often remain unknown in their nature, and may occasion errors of diagnosis: for instance, cephalalgia in chlorosis, the clonus in hysteria, &c. In the last-named disease, pain appears as one element of a more general disturbance of the nervous system. Increased sensibility thus gives to all diseases with which it is connected special characters; it modifies their symptoms, interferes with their regular progress, and gives rise to particular practical indications. This is not all: *hyperesthesia*, at first the only morbid manifestation, may after a time disturb the circulation of the blood in the part it has invaded, and occasion congestion or alterations of nutrition of various kinds. Other nervous accidents may also be the consequences of *hyperesthesia*: thus great pain is not unfrequently the cause of delirium, and of intellectual aberrations: it may also produce convulsions, or diminution of activity in the accomplishment of the functions of the muscular system, even of organic life; hence palpitations of the heart, or arrest of the contractions of that important viscus, and consequently pothima, during which death may occur.

Contractility is the third vital property which is presented to our study; and we prefer, for reasons which will appear obvious, to use the word *motility*. Independently of chemical or physical operations, motion in living bodies recognises four causes—tonicity, contractility, expansibility, and vibration.

Tonic motions are neither very readily appreciable nor susceptible of any great development; they consist in the constriction of solid parts deprived of muscular envelopes. Their result is the diminution of cavities, and the consequent expulsion of fluids contained. In the skin, particularly of the scrotum, that property is manifest: we observe it in the parietes of excretory ducts and of small arteries. In large arteries, tonicity is not very evident: after death the diminution of their diameter is due to elasticity; and the curious experiments of Tiedemann, Müller, and others, have established that, during life, large arteries, in the accomplishment of their functions, diminish more in diameter than after death: the difference being due to the presence of tonicity. Schwann, in experimental researches proved by Müller to be correct, has shown that if minute arteries, meandering through transparent parts, be placed under the microscope, and put in contact with cold water, they will be reduced to one-half or one-third of their size, which they slowly resume in the course of half an hour, when the refrigeration has been removed. The smaller the artery, the more distinct the constriction. Nothing of the kind is observed in small veins. We may now, to a certain extent, account for the local action of styptic or astringent substances on our tissues: they throw tonicity into play. The nervous system is not

without action upon the manifestations of that property, *e. g.*, cutis anserina from mental emotion. Tonicity is, of course, more or less developed, according to the conditions of strength or weakness, of age, sex, and constitution of each subject. Its energy may be morbidly increased or diminished; to its diminution some passive forms of congestion must be referred.

The motions due to contractility are more appreciable, though not more important, than the former. Muscular fibre is their necessary agent; and they can be produced only when the fibre receives arterial blood, and nervous influence. Hence the state of the nervous system will have much to do with their modifications. The enormous development of muscular contractility in hysterical attacks is a striking illustration of the fact. Changes in the composition of the blood will likewise influence the alterations of contractility; and, as a proof, we need only remind you of the deficiency of muscular action in scorbutic and chlorotic patients. Contractility may be perverted: in the muscles of relation we may find it explained by anatomical changes of the nervous system, or by sympathetic action of the brain, as it is often observed in children; or by no appreciable anatomical alteration whatever, as in hysteria. As to the muscles of organic life, they are often seen to contract with morbid energy from the excitement of their membranous linings, or even from simple disturbances of innervation in the heart. Perversion of contractility is met with in chorea, in catalepsy, &c. Muscular trembling is brought on by causes of very different nature—such as age, intemperance, inhalation of mercurial vapour, &c. The diminution or total disappearance of contractility may be due to physical changes in the nerves or nervous centres, or even to a dynamic disturbance of the nervous system: in hysteria, paralysis is not uncommon; great impoverishment of the blood may also occasion it. In his interesting researches on inanition, M. Chanssat has seen, in animals, paralysis of the posterior extremities produced by prolonged abstinence from food.

Expansibility is the special property of erectile tissue. The capillary system has been said to be possessed of it, and a theory of congestion and inflammation rests upon the supposition; to us it is anything but proved.

Microscopic research shows on the skin* of inferior, and the mucous surfaces of all, animals the presence of a vibratile movement, caused by the agitation of minute bodies, analogous in appearance to lashes. After death these motions persist as long as muscular irritability; and electricity has no influence on their production. Narcotics—opium, belladonna, nuxvomica, prussic acid—do not modify them; but these motions are disturbed by acids and alkalis; blood excites and bile arrests them. They are, in all probability, subservient to the displacement of fluids within our body.

MEDICAL PERIODICALS.

(From the *Revue Medico-Chirurgicale*.)
POLYPUS OF THE RECTUM AND FISSURA ANI, IN CHILDREN, BY DR. PERKIN.—The characteristic symptoms of these affections in children appear to be the excessive constriction of the sphincter ani, and the slight hemorrhage which in both accompanies defecation; but they can be distinguished from each other only by the results of ocular inspection. Two cases of fissure are related—observed in the words of Professor Trousseau, and cured by the injection of a solution of extract of rhubarb (1 gramme to 100). In one case the treatment was successful in three days, in the other in nine. A case of polypus of the rectum is also brought forward, observed in a child two years and a half old. The treatment, successful in this instance, and recommended by the author, is the rupture, with the fingers, of the pedicle of the tumour.

GOUT AND RHEUMATISM, BY DR. BUCKLER, OF BALTIMORE.—The author recommends the exhibition of phosphate of ammonia in the treatment of these affections, and brings forward four cases

in which that medicine produced most beneficial results. The theoretical object which the drug is expected to accomplish is to decompose the insoluble urate of soda, which forms the deposits of gout, into phosphate of soda and urate of ammonia, both soluble, and which, therefore, may be readily eliminated by the secretions. The dose employed is 3j. daily, in solution in water.

TRAUMATIC HERNIA OF THE TESTIS, BY M. MALGAIGNE.—Two interesting cases are related by M. Malgaigne, in which the testis was expelled from the scrotum through division of its anterior wall. The progress of cicatrization of the wound, far from causing the spermatic gland to return to its natural cavity, increased gradually the deformity; and M. Malgaigne was obliged, in both instances, to employ a practice which proved successful, and which he recommends in similar cases, although he has not found any authority for it in surgical works—viz., to dissect the scrotum, and there make a bed for the testis, into which the organ shall be replaced and maintained by a sufficient number of sutures.

ON SIMULTANEOUS DOUBLE AMPUTATIONS, BY DR. BROUZET, OF NISMES.—After relating a case of success of this practice, Dr. Brouzet, in opposition with Boyer, Velpeau, and others, recommends the simultaneous removal of two extremities, in chronic as well as in traumatic lesions. The editors of the *Revue Medico-Chirurgicale* approve of the practice only in traumatic injuries.

A letter is published in one of our political contemporaries (*Galignani's Messenger* of Feb. 18), in reference to the discovery of the stupefying properties of ether. It is claimed by Dr. H. Wells, who states that in November, 1841, he made known the results obtained by inhalation of exhilarating gas, nitrous oxide gas, and ether, to Drs. Warren, Hayward, Jackson, and Morton, "the two last of whom subsequently published the same without mention of their conference with Dr. Wells."

In the *Gazette des Hôpitaux* of Feb. 16 we find an operation of lithotomy performed on Feb. 4, by M. Guersant, jun., on a child aged eight years. In three minutes insensibility was produced, and the calculus extracted without pain; the child is doing well, and has had no fever. Three other operations, on children, in the same hospital, have been performed without pain, namely, fistula in ano, and two disarticulations of fingers; no secondary fever was observed.

The same journal publishes the *projet de loi*, deposited on the table of the Chamber of Deputies, relative to the practice and instruction of medicine. Many of the suggestions of the *Congrès* have been adopted, and amongst others the establishment of bachelors and licentiates in medicine.

NECROLOGY.—DR. F. D'ARCEY, at Rio de Janeiro in his 39th year. The deceased, son of the celebrated chemist of the same name, was burnt to death by the explosion of the mixture of essence of turpentine and alcohol, used in the lamps, called "lampes à gaz hydrogène." M. D'Arcey, who had been intrusted with a scientific mission by the Minister of Public Instruction, was late interne of the Parisian hospitals, and had distinguished himself considerably in several concours.

D. MCCARTHY, D.M.C.

Great Britain and Ireland.

CAUSES OF DENTAL CARIES.—MR. TOMES attributes this chiefly to the action of a free acid, whether in the saliva or in the food. He believes that the dentine, from abnormal action, loses its vitality, and with the loss of vitality the power of resisting chemical action; and consequently the dentine is, under favourable circumstances, decomposed by the fluids of the mouth. In reply to the postulate, why, as the decomposing agent enters through the enamel, is it that that tissue is not the first to suffer? he says:—"Strictly speaking, it may be the first;

but, as a much stronger solvent is required, or the longer application of the same solvent, to produce similar impressions on the enamel, the effect is first produced in the dentine." If we place a tooth in a weak solution of muriatic acid, we shall find that the exposed dentine is affected before the enamel, and the exposed dentine before that covered by the enamel. The saliva is in many cases, where decay is rapidly progressing in several teeth at the same time, strongly acid. After salivation this is particularly the case. There is a sufficient amount of acid in our food to effect the slow decomposition of dead dentine. The mineral acids, taken medicinally, produce the same effect.

DR. HAKE'S METHOD OF TREATING PROLAPUS ANI consists in returning the bowel or hemorrhoidal tumour with great care after the daily motion; in assisting its return by means of soap lather; in applying a coil of moist sponge firmly upon the anus, and, while retaining it there with one hand, to bring the nates together by means of a broad strip of adhesive plaster, as in approximating the edges of a wound. The sponge should be four or five inches long, an inch and a half wide, and half an inch thick—the more elastic the piece the better; this is to be rolled in a damp state, tightly, so that the roll, if relaxed, would be ready to spring back into its full length—its length, when thus rolled, will of course be an inch and a half. Vinegar and water is recommended as one of the best astringent lotions.

PAINLESS OPERATIONS BY THE VAPOUR OF SULPHURIC ETHER.—With regard to the claim of priority in the adoption of ether in this country, Mr. Brett claims to be the first to prove its value in the delicate operation of extraction of the cataract. We must add that some of the newspaper reports, to our certain knowledge, have been much more flattering than the facts which we have witnessed at several of the operations at the West-end hospitals.

M. Malapert, knowing the poisonous properties of the saponaria officinalis, and the corn-cockle (*agrostemma cethago*), and considering that these properties might depend on the saponine, thought that other plants of the same family ought to contain that principle. He, therefore, sought for it in different parts of plants belonging to the natural order caryophyllaceae. He ascertained that the different parts of the plants did not always possess the same properties. The seeds of the *agrostemma* contain saponine, but it was only contained in the cotyledons, together with a mild, yellow, saponifiable oil, and a matter which became yellow under the action of alkalis.

The roots of the same plant contained much saponine from the time of growth to that of maturation of the seeds. The stems, leaves, and calyces did not contain it, or at least in inappreciable quantities; it was, however, discovered in the ovaries, even before the expansion of the flowers. It was produced in these different parts of the plants in greater abundance in proportion to their growth till the ripening of the seeds, which explains the fact, well-known to agriculturists, that cows suffer no inconvenience from eating the plant before flowering, while the secretion of milk diminishes, or even wholly ceases, in these animals, after eating the plant in flower or fruit for several days.

The *allene nutans* contains as much saponine as the *saponaria officinalis*, but M. Malapert discovered this principle in every part of the plant except the seeds. He has discovered the same principle in the cultivated and wild pink, and also in the double varieties; but it is not equally distributed through the whole plants. It is abundant in the roots; in small quantity in the leaves and stems. It was not discoverable in the petals or seeds. The *lychnis divica*, *allene inflata* also contain saponine; but it was not to be found in the *stellaria holostea* or *stellaria media* (chickweed). From the quotations cited by M. Malapert, from different authors on *materia medica*, that all the plants containing saponine, such as the different species of *lychnis*, the horse chestnut, &c., possess peculiar properties,

far from being at present ascertained with exactitude, which deserve the attention of the physician. It is well known that the red and blue ichthius (mearou) poison horses, dogs, and birds; that the saponaria destroys fowl; that the horse-chestnut, when not deprived of its bitter principle (saponine), prevents fowls from laying their eggs; that the seeds of the agrostemma kill dogs and poultry, and that they prove poisonous to man; that the plant in flower or fruit prevents the secretion of milk in cows; that these animals eat it mixed with other plants, and are not desirous of it. We are far from agreeing as to the mode of action which this principle, and the plants containing it, exercise on the animal economy, and consequently on their medical properties. The ancients attributed to all the plants which contain saponine the power of resisting poisons, of curing the bites of venomous animals, and even hydrophobia; the moderns, that they possess only diuretic and sternutatory properties. Setting aside the exaggerations and imaginary statements of the properties of saponine, the apparent active properties, its injurious effects when accidentally mixed with the food of animals, are sufficient motives for presuming that it might be useful in medicine. In calling the attention of experimentalists to this substance, and ascertaining more directly its properties, M. Malapert has performed a useful task.

Alum in Pertussis.—The fittest state for its administration will be a moist condition of the air-passages, and freedom from cerebral congestion; but an opposite condition would not preclude its use, should this state not have yielded to other remedies. Its laxative effect obviates the necessity for aperient medicine. Dose for an infant, two grains, three times daily; and to older children, four, five, and up to ten or twelve grains may be given, mixed with syrupus Rheodas and water. It is seldom disliked.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—FEB. 9.

MR. ARNOT in the Chair.

AN ACCOUNT OF A CASE OF ENCEPHALOID DISEASE OF THE HEART. By EDW. L. ORMEROD, M.B., Demonstrator of Morbid Anatomy at St. Bartholomew's Hospital.

The subject of this communication was a man, aged forty-eight, who had had his right testicle removed, for what was supposed at the time to be simple enlargement of the organ, in August last. Shortly after the operation a tumour appeared in the epigastrium, but the wound healed rapidly and he returned to his work. In the course of a week or two he had to give up work from debility, and came into St. Bartholomew's Hospital, under the care of Dr. Roupell, for the last fortnight of his life.

The chief point of interest concerning the tumour in the abdomen was the fallacy thrown over the diagnosis by the discovery of pus in the urine, a fact explained after death by the existence of suppurative nephritis in the right kidney. On examination of the heart, a systolic murmur, of a musical character, was heard at the apex, and a blowing murmur at the base prolonged equally along the aorta and the pulmonary artery.

On examination after death, a large tumour was found to extend down the front of the spine, but loosely attached to it, traversed by the aorta and ascending cava, the cavity of the latter being almost obliterated by pendulous, flocculent masses connected with its walls. The right common iliac vein was ulcerated, the left obstructed by a laminated coagulum, the circulation being apparently maintained by enlarged lumbar veins. None of the abdominal viscera were implicated.

The right ventricle of the heart contained a mass of encephaloid matter, of a lobulated form, springing from its anterior wall, one lobe extending into the ring of the tricuspid valve, or at least intervening between its tendinous cords, another reaching up nearly to the pulmonary valves, and a few more, smaller ones, lying

towards the apex of the heart. The wall of the ventricle was a good deal changed at the point whence the lobule sprang; elsewhere it was healthy. The tumour consisted of nucleated, with some caudate, cells, dispersed through a loose amorphous tissue.

The author limited his observations to two points,—the auscultation of the heart, and the nature of the tumour there. With regard to the auscultation, this case seemed to show that the presence of a growth of this kind, even of such a size, could not certainly be made out during life by any signs proper to the tumour itself; it could only be detected, as any other foreign body might be, by its accidental interference with the functions of the heart. It was casually illustrated, while on this part of the subject, how cancer of the pericardium might also exist without being detected by auscultation.

With regard to the nature of the tumours (which part of the paper was omitted, on account of the length of the following interesting paper) the author endeavoured to place in the order of their different stages of growth the few cases of endocardial cancer hitherto published. Presuming an analogy to exist, according to Rokitsky, between these tumours and the globular vegetations of Laennec, there seemed to be a regular gradation from the masses which hang on the endocardium, as if deposited there by the blood, to the lobular growth, which, true to the nature of cancer elsewhere, had destroyed the muscular structure of the heart in one part of the preparation exhibited to the society.

CASE OF INTERNAL STRANGULATION OF INTESTINE RELIEVED BY OPERATION. By GOLDING BIRD, A.M., M.D., F.R.S., Assistant Physician to Guy's Hospital; and JOHN HILTON, F.R.S., Assistant-Surgeon to Guy's Hospital.

Dr. Bird remarks, that the attention of the society having been lately occupied with the consideration of the practicability of diagnosing the seat and nature of the obstruction in cases of internal strangulation, with a view to its relief by operation, he ventures to hope that the history of the following case will not be considered devoid of interest.

Dec. 21st, 1846.—Dr. Bird was called to Boeking, in Essex, to see Mr. C—, a young gentleman twenty years of age. Eight days previously he was as well as usual, having merely had constipated bowels for a couple of days, when, in the morning, whilst in bed, he became sensible of slight dragging or sense of giving way about two inches to the right of the umbilicus, towards the spine of the ileum. This sensation was soon replaced by a sense of soreness and tenderness. During the following six days, nothing passed from the bowels except with the aid of a copious enema. Purgatives and a tobacco enema failed in procuring stools. Three days previously sickness commenced; a sense of uneasiness and distress was produced by firm pressure on the spot where the dragging was first felt; the abdomen was flat and collapsed. On inquiry it appeared, that when a child he had been the subject of mesenteric disease, and some years afterwards, of an ailment, supposed, from the symptoms, to have been peritonitis. The absence of hernia, as well as of any previous hemorrhage from the intestines, or of exposure to the influence of lead, the improbability of the presence of malignant disease, proved the non-existence of the most ordinary cause of insuperable constipation. Recollecting the dragging sensation and previous existence of peritonitis, Dr. Bird ventured to give an opinion that the mechanical obstruction depended upon a knuckle of intestine becoming strangulated in some manner under a band of false membrane. The character of the vomited matters and the empty state of the cecum and colon at once referred the seat of obstruction to the small intestines. Trial was made of metallic mercury, after which the pain and vomiting ceased, and no important change occurred until Dec. 26th, when pain and vomiting returned. The propriety of an operation was entertained; and Dec. 26th,

the writer requested the assistance of Mr. Hilton for this purpose, and they arrived at the patient's house at nine o'clock P.M., being just fifteen days from the commencement of the illness. The abdomen was scarcely more distended than on the 21st, but the muscles were more irritable, assuming a state of spasmodic contraction on the slightest manipulation. No great uneasiness experienced on pressure. Pulse 90; skin soft and cool, and tongue moist. The patient was placed in a room in which a temperature of 88° to 90° was maintained.

Mr. Hilton states, that having arrived at the same conclusion respecting the nature and seat of obstruction as that described by Dr. Bird, he fairly represented the various arguments and facts for and against an operation to the patient, who expressed himself decidedly desirous of the attempt being made to relieve him. An incision was made from the median line to within an inch of the pubic symphysis, and the abdomen opened. Several convolutions of distended and congested small intestine so completely blocked up the opening, that it was necessary to enlarge the incision for about one inch and a half above the umbilicus. After dividing a band of adhesion between two portions of small intestine, and making a careful search in different parts of the abdomen, Mr. Hilton found on the right side about six or seven inches of ileum in a state of strangulation, having passed through an annular opening formed in part by another portion of the same small intestine, and by some old membranous adhesions to the hrim of the pelvis, over the external iliac bloodvessels. By gentle traction on the strangulated intestine at the opposite side of the opening through which it had passed, Mr. Hilton succeeded in liberating it from its incarcerated position. The intestines were replaced with some difficulty, and the abdomen was closed by a continued suture. After the operation, which lasted about an hour, the patient was somewhat collapsed, but there was no marked anxiety of countenance. He afterwards became restless and delirious, and died about nine hours after the operation. On examination of the body, several strong cellular adhesions were found between the convolutions of the intestines. The cecum and colon were distended with feculent matter. Mr. Hilton regards the direct results of the operation as very satisfactory, and in a surgical aspect, successful. The hemorrhage and vomiting ceased; the obstruction was relieved, and feculent matter had passed as far as the upper part of the rectum. So long as any doubt remains as to the seat of obstruction, the author thinks it the safer plan to adopt the median section of the abdominal parietes. After noticing the disadvantages arising from the patient's friends not consenting to an operation at an earlier period, he observes, that the circumstances of the case fully justified the proceeding which was adopted; and, notwithstanding its fatal termination, he would advise the same plan to be pursued in a similar case, provided the indications be as clearly expressed. Mr. Hilton remarks, in conclusion, that he believes this to be the first recorded instance of any surgeon in this country having succeeded in his attempts to relieve an internal strangulation by an operation.

Mr. Ferguson thought the operations which had been so frequently performed for removal of enlarged ovaria had proved that there was not such risk on opening the peritoneal cavity as had been generally supposed, but that it was an important matter to decide, in the case given, as to where the incisions should be made. He thought that, as a general rule, the linea alba should be selected, and that the surgeon here had very judiciously chosen that part.

Mr. Bransby Cooper contended that there was no analogy between cases similar to the one detailed and those in which ovarian cysts had been removed, for the peritoneum in the two cases was altogether in a different condition. He thought that the danger of opening the peritoneum had been underrated, and referred to our success in those cases of hernia in which the

strangulation had been relieved without opening the sac, as evidence of the truth of his remark.

Mr. Quinn entertained the opinion that an operation would be justifiable if the internal strangulation were clearly ascertained.

Mr. Hilton felt pleased at finding that the gentlemen agreed, on the whole, in the propriety of doing what had been done in this case; and that their remarks might be made available in recommending such a proceeding in another case of the same kind.

SURGICAL SOCIETY OF IRELAND.—JAN. 23.

J. W. Cusack, Vice-President of the College, in the chair.

Mr. Tufnell read a report on some experiments with the vapour of ether, made with a view of testing its effects on individuals in their natural healthy condition. The experiments, four in number, were performed on soldiers, some of whom were of robust habit, while in the others the constitution was of rather an opposite character. These modifications of constitution were attended with corresponding modifications in the results of the experiments with which our readers are now sufficiently familiar.

Sir Philip Crampton next exhibited Mr. Squire's apparatus for the inhalation of ether.

CASE IN WHICH LARYNGOTOMY AND TRACHEOTOMY WERE PERFORMED.

Mr. M'Namara related the following cases. A child while eating some bread stooped to pick up a plaything, in doing which the bit became impacted in the œsophagus. Symptoms of suffocation came on immediately; but, owing to some untoward circumstances, a considerable time elapsed before the child was seen by Mr. M'Namara. When first seen by him, death had almost put an end to the little patient's sufferings. The whole body was in a perfectly rigid state, the eyes were protruded from their sockets, in fact life was on the point of closing.

Mr. M'Namara turned to his study-table for a gum catheter, or any other means that might be at hand, to enable him to push down the foreign body, which he was just able to touch with the fore finger. As nothing of the kind was at hand on the instant, however, and seeing that even a few seconds delay must be disastrous, he took out his pocket-case and at once opened the larynx.

For a short time the result was extremely satisfactory: the little girl gradually recovered; the respiration came round; the body lost its rigidity; the eyes assumed their natural appearance; and sensibility was soon so far restored that the child put out its tongue when asked.

Symptoms of obstinate respiration now reappeared, however, and, with the ear applied to the chest, it became evident that the right bronchus was obstructed by something that entirely prevented the access of air to the right lung. In a consultation with Dr. Porter, jun., and Mr. Rumley, who just came in, it was decided that tracheotomy was now the only chance, and as such, though with hardly a hope of any benefit whatever, the trachea was opened by Mr. Rumley. The child soon after sank and died.

In examination, a bit of hard bread, not crust, was found in the right bronchus, which it may be supposed was detached from the bit impacted in the œsophagus, while the latter lay high up in the neighbourhood of the glottis.

In the difficulty of accounting for the unfortunate termination of the case from the mere obstruction to respiration in one lung, Mr. M'Namara is inclined to attribute death to coma, induced by an absence, for so long a time, of arterialized blood in the brain.

GOITRE TREATED BY SETON.

Dr. H. Kennedy related the following case:—

A woman, aged thirty-five, nine years married, and mother of four children, applied to him on account of enlarged thyroid gland, in November, 1845. Of late years she has lived in Dublin, and always considered herself healthy. In the year 1832, thirteen years before his seeing her, the gland began to enlarge; its growth was very slow

until the last year or so, when it began to increase in size rapidly. When first seen by Dr. Kennedy the tumour was at least the size of the largest orange, or small melon, very hard to the touch, as if solid, but was divided into two portions, of which that on the right side was much the larger.

Its bulk did not vary during the menstrual periods. It was not, however, on account of the bulk of the tumour that Dr. Kennedy was consulted, but because of the dysphagia with which it had been attended, in some degree, from an early stage, and which had latterly become distressing. She now stated that the act of swallowing any solid required care, and that large mouthfuls occasionally, though not always stopped, the stoppage being referred to the seat of the tumour. The tumour had been seen by other gentlemen, and had, it appeared, been treated for the previous nine weeks by the external and internal use of iodine, but the woman considered it still increasing.

Viewing the circumstances of this progressive increase of the tumour and dysphagia, the failure of the iodine treatment, and an anxiety on the patient's part to have something done, Dr. Kennedy adopted the treatment by setons as holding out the best prospect of success, having first brought the woman's health into the best possible condition, in order to guard against the occurrence of any untoward event. On the 30th of November, 1845, a common curved needle, of the largest size, nearly full of double threads of silk ligature, was passed, from below directly upwards, through the anterior portion of the tumour, about half an inch from the middle line of the neck, and including a space of at least one inch and a quarter between its entrance and exit. The patient was desired to stay in bed for two days, and to keep a poultice constantly applied. No unpleasant effect whatever followed. Suppuration soon became established, but so trifling a degree as not to affect the bulk of the tumour. At the end of ten days the seton was withdrawn, the poulticing, however, being steadily continued. In three weeks a second seton was introduced, double the thickness of the first, in the same direction, but further from the middle line, and included a larger space between its entrance and exit. The treatment otherwise was the same as before. Next day a considerable amount of constitutional irritation had arisen: the pulse 130; tongue furred; skin hot; with burning thirst, and other febrile symptoms—which, however, with simple treatment and three or four days' rest, subsided, and suppuration became much more fully established than in the first instance. While the febrile symptoms lasted, the tumour was much increased in size; and the swelling not only engaged the neck, but extended to the soft parts below the clavicle for a considerable distance. The suppuration being considerable, it was deemed advisable to remove the ligature in twelve days. In a period of four months, that is up to April, 1846, nothing more was done than continuing the poultices, and attention to the general health; and in this time very perceptible alterations had taken place in the part of the gland lying to the left of the middle line, and about an inch to the right. It had lessened very considerably at these points, and become remarkably hard. The part of the gland lying furthest to the right of the middle, however, remained entirely unaltered. Indeed—whether it arose from the diminution of the other portion of the tumour or not—yet so it was, that the part alluded to seemed to have grown larger, at least it was thrown more strongly into relief, than at first.

The third and last seton was now passed in the middle of April, 1846, its direction being upwards and outwards, so as to ensure its traversing the larger axis of the remaining portion of the tumour. It was of much larger size than either of the former ones, probably four times larger. The external jugular vein, passing at its point of exit, had to be avoided. The needle was a common packing-needle, prepared at the point and edges for the purpose. In sixteen days, the suppuration being now considerable, this last seton was withdrawn, and its employment was followed by no unpleasant effects. At the end of between three and four months, after a similar process as before—hardening and gradual contraction of the swelling—the

tumour had nearly disappeared; and now (Jan. 9) no traces at all of it remain.

Dr. Kennedy thought this case worth bringing under the notice of the society, as cases of the kind are not of frequent occurrence—such, at least, as it would be justifiable to operate on. He had not himself seen a case so treated here, though he believed it had been done in some of the Dublin hospitals.

In one of the volumes of "The Medical-Chirurgical Transactions of London" would be found an interesting account of some cases of the sort. Cases calling for direct interference have much decreased in number since the introduction of iodine into practice. He was indebted to the kindness of Surgeons Hughes and Bannan, of Jervis-street Hospital, for an opportunity of seeing a very remarkable case of great general enlargement in and about the thyroid gland, in which the use of iodine was followed by very marked effects. But iodine will not always succeed; on the contrary, in the foregoing cases the tumour increased under its use.

Dr. Kennedy still felt in doubt as to the real nature of the tumour in the foregoing case. Before the passage of the first seton it had every appearance of being a solid one, but on the introduction of the needle it gave exit to a small quantity of fluid very like ink, from which it might be inferred to be encysted. No subsequent occurrence, however, tended to such an inference, and his present impression was, that but a small portion of the tumour was encysted, while the remainder was solid. The introduction of the last and largest seton strongly conveyed to his mind that the needle was passing through a solid tumour.

It was worthy of remark, he said, that it was the second seton which produced, for a few days, symptoms of high constitutional irritation. One would rather have expected these to have arisen from the first, because it was the first; or the last, on account of its much larger size. The fact appeared to point to some particular state of the system as the cause, though what that state was he could not determine.

He need hardly observe, he said, that in bringing forward the case, he was far from a wish to make it a rule for the general treatment of similar cases: for, though the operation is in itself simple, it is not to be undertaken on light or trivial grounds. It might, he conceived, be followed by very untoward circumstances—indeed he believed such have occurred—not to speak of the great length of time which the process of cure occupies, and which in the present case was nearly nine months. Neither must the constant poulticing and prolonged suppuration he lost sight of, and occasionally the very unpleasant smell.

Not being very certain what the result of the case might be, Dr. Kennedy, unfortunately, had not cast taken of the tumour in the beginning. He might state, however, that at the commencement the patient was seen frequently by Dr. Clarke, of Herbert-street, who kindly assisted him, and was much interested in the case. In the progress of cure it was also seen by Drs. Bullingham and Jonathan Labatt; by Surgeons Hughes and Bannan; and that day by his friend Dr. C. King.

No deformity whatever remains, and scarcely any marks where the setons were passed. The patient now says, too, that she is scarcely conscious of any difficulty of swallowing.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—ST. VALENTINE'S DAY.

By J.E.

Long previous to three o'clock, the hour appointed for the delivery of this annual valediction upon the memory of John Hunter, the small, inconvenient, and ill-ventilated theatre of this institution was crowded to the ceiling. Whether this attraction was due to the expectation of a scene in which the discontented members should be actors, or to the popularity of the orator, we will not determine; but it is certain that the provident and prudent council had made arrangements by which any demonstration of public feeling should be neutralized. In various

parts of the theatre well-drilled platoons of *claqueurs* were skillfully placed, so that, by an uproarious applause, they might drown any expressions of discontent.

In the selection of their advocate, also, the council evinced a good deal of shrewdness. Mr. Green is known to be, in his feelings and conduct, the perfect gentleman; and, by his addition to an eccentric kind of philosophy, has possessed himself of so peculiar a phraseology that he can convey to an audience the most unpalatable assertions in a guise the most perfectly intelligible.

This kind of accomplishment, now that the glory of the triumph achieved by the council over the divided and dispirited commonalty has been tempered by time, was thought more suitable to the occasion than the vulgar and insolent perspicuity of Lawrence.

The victory is now undisputed; the members at large are contented with their serfdom; and it would have been impolitic, by new insults, to provoke into action any lingering leaven of independence that might still be found in the degraded mass of members.

Considerate duces, et vulgi stante corona. Four rows of seats were kept vacant for the use of the fellows, who very properly object to sitting promiscuously with the *canaille* of the college. Different classes of men exhibit different virtues; and it is very becoming in the chosen few to feel a disdain for the crowd, whose chief virtue happens to be that which is exemplified in certain quadrupeds who have tasted the whip.

The council mustered strong, and some of their members received the ready homage of the *claqueurs*. Mr. President Lawrence, who looked in his red gown like a respectable parish beadle, was greeted with certain significant marks of disapprobation; but these wholesome expressions were neutralized, in a great measure, by the laudatory performances of the "trained bands."

The oratorical performance of Mr. Green proved to be, what our recollection of his former address led us to anticipate, a metaphysical *mélange* in which a hazy and obscure verbiage would be found to cloak a considerable amount of objectionable matter. So perfectly transcendental as to sense, indeed, was the whole effusion, that the *claqueurs* were at first ludicrously at a loss when to applaud. After a time, however, they discovered two occasions, which served as clearly as the *baton* of a conductor to regulate the concert of their "sweet voices." Whenever the orator made a Latin or a Greek quotation, or when he bowed his head to a given distance from the cushion, were incidents which served as signals for applause. Mr. Green possesses many of the qualities which the ancient rhetoricians enumerated as necessary to the orator. He stands six feet four inches in his stockings. He has a handsome and dignified countenance, an agreeable manner, perfect self-possession, a sonorous voice, an easy elocution, and the most continuous and integral *copia verborum*. Such a casket is fit for the custody of jewels; but, alas! if it should contain nothing but beads and pebbles?

The mild and intellectual bust of Hunter seemed to regard the whole spectacle with a smug indifference. Could the Witch of Endor have, for *vaen* *ec*, raised the great original, and placed him in the seat of "Mr. Bumble Lawrence," we would have predicted, without fear of contradiction, that the *etherizing* diatribe of Mr. Green would have speedily dismissed him from the earth in a second fit of apoplexy.

Generalities are proverbially barren; and Mr. Green, by his fondness for abstract notions, far-fetched similitudes, and florulent metaphors, involved himself in a kind of scientific cuphuism, which was perfectly impenetrable to the majority of his audience. We will endeavour, on another occasion, to translate, however, for the amusement of our readers, a few of the string of concepts which formed the subject matter of the oration.

He began by likening the series of orations,

delivered in honour of the presiding Lar of this temple of surgery, to a *cairn*, or heap of stones, raised in early times to the memory of departed heroes. He now threw his stone on the epitaphial pyramid of Hunter.

"Hunter was the father of scientific physiology, which was the basis of all surgery. He was the originator not merely of an orderly arrangement of facts in physiology, but the founder of a science 'in the unity of a scientific idea.' He had demonstrated 'life' to be a *law* and a *power* antecedent to organization, and his eloquent museum beautifully displayed the development of this principle of life, from the simplest to the most complicated forms of living beings. He had first applied an enlightened physiology to explain the phenomena of surgery, and thus reduced a conjectural art to the authority of science.

"But Hunter was a man of splendid genius. How, then, could he be held up as an exemplar to ordinary men? The solution of this question depended upon the definition of genius. Was this attribute of the mind an extraordinary endowment vouchsafed to a few favoured individuals? or was it a result of the cultivation of good talents not differing in kind from such as are conceded to men in general?

"Whichever way the problem may be solved, the effects of a liberal education are equally beneficial, for no powers, without great labour and perseverance, have ever sufficed to the production of great works. Even the genius of Milton could not have created his immortal epic if he had not, by assiduity in his early life, acquired a perfect control over the riches of language. Whether or not powers of originality could be conferred by training, it was certain that the efficacy of all the mental powers might be enhanced by a proper system of education, and the usefulness of the human agent consequently increased."

The orator said his intention was not merely to pronounce a eulogium upon Hunter, as that was a theme which had been exhausted by his predecessors, but to vindicate the conduct of the council in founding an order of fellows who should excel the remainder of the college, not only in professional attainments, but in general literary and scientific accomplishments. His conviction was, that a liberal education would not merely improve their efficiency as surgeons, but raise them in the scale of social respectability.

None of Mr. Green's auditory would think of denying these very palpable propositions, because it happens to be notorious that the social exaltation of the profession, and their concurrent improvement in science and literature, are entirely due to the general practitioners, who form the body of the college.

Mr. Green quietly assumed, throughout his address, that the great body of the commonalty was buried in Cimmerian darkness, and that the council constituted the sole focus of light.

This must be admitted to be a pretty audacious assumption, when the converse is so obtrusively true, and it is known that the "pressure from without" has alone forced and shamed the council into the only measures of improvement they have adopted. How the creation of an order of fellows was to secure the social and scientific elevation of the college more certainly than rendering the examination of *all* members more searching and stringent, Mr. Green did not attempt to prove. His purpose was not so straightforward. By a dazzling description of his "*beau idéal*" of a liberal education, he wished to seduce the attention of the members from the real point at issue. And a very beggarly "jackdaw" of a "*beau idéal*" does this prove when stripped of its fine feathers. Afraid, however, of absorbing all the glory of the "*beau idéal*" in himself, the champion very modestly ascribes a portion of the merit to "his revered master and friend S. T. Coleridge," "whose memory shall not pass away, and whose name shall live from generation to generation."

Now, every body knows who poor Coleridge

was. He was a writer of Tory leaders in the *Morning Post*, and an inveterate opium eater; a man endowed with considerable genius, which was much counteracted by vicious habits, and was consequently prolific of nothing but *fragments*, whether poetical or metaphysical. He must, therefore, be a very sorry authority for any system of education.

"The object of all education," says Mr. Green, upon the authority of Coleridge, "is to develop the individuality of man." This is realized by the concurrent triumph of free will and reason, which in their union constitute a *moral potentiality*.

"The realization of this perfect individuality is never attained by frail humanity; the most distinguished of mankind for energy and influence over their fellows, Luther, Milton, and Dante, do but approximate to this goal."

"It is a gross mistake to suppose that any knowledge can be *impressed* from without; education consists in the development of powers within the microcosm of the mind. It is by reflection upon the acts of our own consciousness—a power which is matured slowly—that we acquire a knowledge of our own powers." "When man is occupied in the study of the phenomena of his own being, his contemplation of these phenomena adds a new phenomenon to the list already under his inspection: it adds the new and anomalous phenomenon that he is contemplating these phenomena."

"In carrying forth the physical sciences, man very properly takes no note of his contemplation of their objects, because this contemplation adds no new fact to the complement of phenomena connected with these objects. But in constructing a science of himself, man cannot suppress this fact without obliterating one of his own phenomena."

"The act of philosophizing is the act of contemplating our own natural or given phenomena. But the act of contemplating our phenomena unsystematically is no other than consciousness. Thus, in attending to the fact which philosophy brings along with it, we find that philosophy and consciousness become identified; that philosophy is a systematic or studied consciousness; and that consciousness is an unsystematic or unstudied philosophy."

"By this exercise of reflection we are made familiar with those two intellectual powers which form the peculiar excellence of the human mind, and are the factors by which our various kinds of knowledge are accumulated and appropriated to ourselves. These are '*abstraction*' and '*generalization*;' without these faculties man would be utterly incapable of constructing a science, of conceiving an ideal unity, and civilization could have never existed, because no one generation could have improved upon its predecessor."

Mr. Green now drew an outline of the whole of human knowledge, and pointed out the share which these faculties, ministered to by reason, (which is simply the power of comparison), exercise in the creation of science. Mr. Green began with the alphabet, "a splendid proof of the activity of the generalizing faculty." He next proceeded to the accidents of speech, which furnish so many indexes of the logical process employed in the development of this knowledge. In this stage he was not very lucid. He defined the class "*substantive*" pretty clearly, but the verb, and minor parts of speech, he left untouched, and gave no description of the distinct provinces of grammar—logic and rhetoric. The acquisition of a new language, he said, was the acquisition of a new limb without its deformity. From the consideration of the *littera humaniores* the lecturer proceeded to treat of natural history in its most extensive sense, including chemistry, geology, mechanics, meteorology, and astronomy; and here he indulged in very tumid expressions, and highly grandiloquent tones, without imparting a single new idea, or one impressive sentiment. The natural history of the human race naturally led to reflections upon the gathering together of nomadic hordes, and the rude commencements of political societies;

upon the use of language as a means of intercourse amongst nations, and its share in the conversion of a barbarous tradition into the authentic records of history. Of the use of language as an instrument of thought he said not a word.

The mathematics were next considered, as a means of developing the intellectual powers; and, though pompously panegyricized, were determined not to be so good an exercise for the generalizing faculty, as logic.

This last art, which is daily practised by every one who speaks and reasons, was defined to be "the art of drawing conclusions from premises." Some trite observations were expended upon the use of this science, as well as upon the obstacles (fallacies) which impede right reasoning. These points will be found better and more fully explained in the works of Whately and Walker.

Having traversed the whole field of natural and metaphysical knowledge, the speaker now turned to the moral nature of man; and we cannot in this province congratulate him upon the perspicuity of his views. Instead of a moral sense in directing conscience, we have the term "moral will" introduced, as something distinct from ordinary volition. He here employs a single term to express a compound fact, namely, the subjection of the will to the moral power. This subject speedily led him to speak of the cognate themes of *natural religion* and *revelation*, and to a desperate effort to conceal the two classes of truths by a natural link. Thus completing, as he termed it, the unity of idea which constitutes the individuality of man.

This is evidently an attempt to revive the theory of Plato, that man, by gaining possession of the "divine idea," acquires the key of all knowledge, and unites himself to the Divinity. "By cultivating this unity of idea, and approximating to the perfection of the 'moral will,' man assimilates himself more and more to the *λογος* who created him." *Ἐν αὐτοῦ ἡν, καὶ ἡλὼν ἡν το φῶς τῶν ἀνθρώπων*, quotes the orator. "In the word was the life, and the life was the light of men." If the truths of revelation could be reached by any logical process, where was the necessity of a revelation at all?

Thus concluded this visionary effusion, which we humbly opine cannot be of the slightest edification to any except, perhaps, to the author of the "infidel lectures," who sat in the red cloak opposite the orator. The whole production was a vain effort to display the learning of the speaker. It exhibited neither ingenuity nor eloquence; it contained scarce a single reflection likely to instruct the medical student, and was devoid of those natural considerations which would occur to a healthy mind on such interesting occasions. Nothing was said by the teacher of the studies best fitted to form an efficient medical character; no rule was given by which to economize mental labour; no maxims promulgated by which the independence of the will was to be realized!

If such as these are to be the exhibitions which the wisdom of the council is to hang out to the world, why, then, let them have rope enough. The contempt of an indignant public opinion will speedily wrench from them an authority which, though they have the insolence to usurp, they have not the skill to handle to any useful or honourable purpose.

The conclusion of the long and tedious harangue was hailed with uproarious applause; and, the red-coated president, upon rising, was saluted with hisses and groans. (E.)

There are of all things two estimates: and, though we can hardly be expected to accept both, there can be no harm in hearing them. Saying this, we must add, that our estimate of the lecture—apart from its medical politics—would be far more genial and eulogistic than that of our correspondent.

APOTHECARIES' HALL.—Gentlemen admitted members on Thursday, Feb. 18:—John Black, Temple Chevallier Paley, Edward Monement, George Pretyman Hubbard, and Anthony Unthank.

TO CORRESPONDENTS.

THE MEDICAL TIMES is the only Medical Journal published at its own Office, and which is free from the control of all Booksellers and Publishers. Gentlemen may procure it by an order on any Newsmen or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carfras, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 13s.; Quarterly, 6s. 6d. No number of the Medical Times can be forwarded, except to gentlemen paying in advance.

ALPHABETIC PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 6s. An allowance is made to the trade.

We regret the delay in publishing Mr. Close's contribution. We shall set ourselves right with our valued correspondent in a few days.

Mr. Chessman, surgeon to the South Hants Infirmary, records to us two cases of surgical operations under the influence of ether. In the one case the patient was conscious the whole time of the circumstances of the operation, though free from pain; in the other he was conscious part of the time. In the one instance an arm was amputated by Mr. Lee; in the other, some diseased bone, by Mr. Bullar.

D. H. G. W. had better consult a bookseller's catalogue, and judge for himself. A preference in the case he names would be invidious.

Subscribers who yet remain on our books in arrears will oblige us by immediately forwarding their remittances to the office.

A. B. C. will find an answer to his question in one of our advertisements.

Fifa.—Startin's inhaler may be procured through any bookseller or wholesale druggist. Our publisher will send the numbers wanting by post, on receiving an order with postage stamps to the amount.

H. R., who wishes to hear of a harmless medicine which shall make him look pale in the face, is informed that his question is one of those that should have the opposite effect on him, and make him blush. It would be no benevolence in us to give our space and time to reply to such inquiries. Common Honesty's indignant protest would be thrown away in print. It is the man's destiny to live on "libel" in one shape or another. The encomiums on our labours receive our acknowledgments.

A Correspondent, who sends us another advertisement of the Silurian, only advertises a gentleman who is sufficiently ready to perform the service for himself.

Mr. Preshaw's request cannot be complied with, from the numerous claims on our space.

Mr. King will find our opinion on inhalers in our last number.

Mr. Davies.—Mr. Tucker Hunt ceased to have any connection with the Medical Times long before the present management commenced.

A Victim.—It is against our principles to play the inquisitor on any gentleman's private practice. If made notorious by public inquiry, we should not then hesitate to give our opinion.

The several gentlemen (some, too, anonymously) who have addressed us on the Hounslow inquest, in especial reference to ourselves and our own labours, are respectfully informed that, while we admit that the vindication of justice through the first court in the kingdom has cost us more money than it should (between one and two hundred pounds), we yet cannot lend our columns to the purposes they kindly propose. We will not even indirectly be parties to any such suggested acknowledgment. We possibly do not deserve it; and if we do—but we have sufficiently explained our views.

Our readers' attention is directed to Müller's magnificent work on *Physics*, commenced in the Pharmaceutical Times of to-day. It will be illustrated by 585 beautiful engravings.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the Science of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract lore of a pedantic and inapplicable lore. Every power of his mind is engaged; he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate, to be EXPERIENCED: each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diploma or license.

Six of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is *bona fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, FEBRUARY 27, 1847.

THE NATIONAL INSTITUTE.

Ὁ πόσις, ᾧ καὶ μεν γε καὶ ὁς μάλα νήπιός ἐστι,
Γνοίη, ὅτι Τρεῖσσι πατὴρ Ζεὺς αἶδος οὐδαίει.
ΙΟΜΕΝ.

It is no new discovery in politics that the multiplication of ruling powers, instead of adding to the security of the subject, only tends to weaken those ties by which his liberty and happiness are held together. Greece had enlightened views of government, but, split into various little states—each having separate interests to maintain, and independent of each other—their energies could neither be consolidated, nor their vices permanently held in check. The Council of the Amphictyons, composed of the wisest and most virtuous men of the republic, it must be admitted, whose decisions were held sacred and inviolable, served, in some measure, to restrain the licentiousness of the turbulent little states; yet even this august assembly was found inadequate to accomplish the end designed, so that one and all, at last, became an easy prey to a more consolidated enemy.

In our system of medical polity there is one glaring defect—a want of unity. We have separate and independent bodies, intrusted with the regulation of our affairs, each bent upon advancing its own interests to the utter subversion of true liberty and honourable elevation of the profession for whom they ostensibly

legislature. In them we have a picture to the life of the Grecian republics, so far as the elements are concerned, which worked their destruction, without the watchful care of a supreme tribunal to direct and control the whole. In these chartered monopolies one principle has been abundantly manifested—a supreme regard of self. It is not to be expected that it would be exhibited in all its native deformity, or there would have been at once such a revulsion of public feeling that even medical colleges would have been unable to resist; such a unanimous cry for justice that tyrant corporations would be compelled to respect; but the monster has been dressed, adorned, and vested with the beautiful garments of patriotism, honour, and good feeling. The cloven foot, however, has too frequently peeped out to deceive men any longer, the veil has been boldly lifted up, and the hideous features have been seen, which have frightened men into a firm resolution to strip off the borrowed raiment, and, so far as possible, leave the monster without one factitious ornament to deceive. Impudence, like charity, can cover a multitude of sins; but our colleges have not had impudence enough to hide all the sins which they have committed. They have been, like the sons of Telamon, armed with brazen shields, yet there have been some arrows shot so true, and so strong, that they have pierced to the very heart, and even now rankle in the wound. It has been already seen that these colleges are not impregnable, that the members are not quite noodles, and that, though they have been shorn of nearly all power, a little has been left which, working gradually, will, like the little leaven, leaven the whole mass.

It is as evident as the simplest equation that our old colleges can never, or will never, do what is required of them by the members of the profession. We want wise and humane counsellors, not supercilious and despotic lords, institutions where the voice of the people is heard, not those which will have none speak but a privileged, self-elected few—where Science is the presiding duty, and the worshippers offer the sweet incense of an enlightened intellect from off the altar of a willing heart; not Mammon, whose cursed thirst for gold leads her to ape Science, that her votaries may be robbed. This these old institutions will never do for us—they are moners long inured to sin, and therefore hardened in it, cunning as the serpents which some of them sport on their shields, and, like them, can be traced by the slimy impressions they leave behind. The delinquents may be brought on their knees by the force of public opinion, and cry with all meekness "Pecuni," there they must be kept chanting their own requiem, till substantial security be taken for their future good behaviour—that they may for ever after keep the peace towards all her Majesty's subjects, and the medical profession in particular, and this can only be accomplished by the permanent establishment of the National Institute.

Nothing less than the urgent wants of the profession could justify the founding of a new college amongst us, as we have already on hand such a stock of the old materials as would glut

any country upon the face of the earth. It is to be hoped, however, that if they are past mending, and if there be no possibility of shipping them to some far-distant clime, that they will at least become "old curiosity shops," where future generations may, for a small sum, view these antique follies, once as celebrated as they were injurious.

In our day the general practitioners are numbered by thousands; and, as a body, they are universally admitted to be gentlemen, scholars, and philanthropists. It is granted that, when the physicians and surgeons received their charters of incorporation, so much could not be said of the multitude who practised the healing art. There were then no barriers to prevent individuals with little knowledge and much brass from using physic, under the false pretence of bringing health to the sick, while the real intention was to extract gold from his pocket. Such a state has passed away, never more to return, and yet the old colleges act, and would legislate, as if patronage and protection were things which we ought not to expect, and certainly do not deserve. They have, to all appearance, lived only to themselves, with closed eyes and open mouths; and the sins of these honorary corporations have brought such mischief on the profession that it has been compelled, in self-defence, to associate in one common brotherhood. It is not to be expected that a commonalty of enlightened minds is to be ruled with the iron hand of despotism, without any effort to be freed from its unmerciful grasp. The Philistines had caught Samson napping, and they tried to bind him with new cords, as skilfully fabricated as any cords could be, to take away his strength; but when the cry was heard, "The Philistines be upon thee!" in a short time the bonds were snapped as if they were very tow. Medical men would have proved themselves "snobs" to the very core, if they had truckled any longer to the corporations, which let slip no opportunity of insulting them, and courted the Home Secretary to put an extinguisher upon them. After this a new Institute was inevitable, if there were to be any exhibition of honour or courage—one which would not be contaminated with the vices of its predecessors, but strong in the number, the affection, the endowments of her sons, would, like another Hercules, cleanse the Augean stables of Lincoln's-inn-fields and Pall-mall. Let us see how far the infant college, baptized with the name of "National Institute of Medicine, Surgery, and Midwifery," is calculated to accomplish these desirable ends. The little stranger is strong-limbed and well formed, and has entered struggling into life with an energy which bids fair for a long and useful existence. To use the pugilistic metaphor of the celebrated "Box" in his account of little Dombey, it has entered the world squaring, not at existence, but at the wall-eyed old corporations, who would have gladly strangled it in the birth.

The new Institute will be no patron of close-boroughism, and will have nothing in its constitution that will admit of its existence. The officers are the public servants of the household, chosen by the members, and responsible to them for the manner in which they discharge

their functions. Their places are to be purchased by the sterling coin which bears the image and superscription of intellect and moral worth, not by a baser metal which nations have invested with a fictitious value merely to facilitate the commercial dealings between man and man. We search in vain for anything approaching to this in our present chartered bodies, the big ones must have all to themselves; and it is rather curious that old Bartlemy and Guy's, &c., should enjoy the unspeakable privilege of begetting these professional magi, who are to astonish the world by their feats in surgery, and the profession by their feats in lawmaking.

The National Institute, moreover, has not only a good constitution, but it will confer collegiate respectability. Now, medical men have a name, and nothing more. The Lincoln's-inn diploma is but a sorry exchange for twenty substantial sovereigns. The new fledged member, leaving the college doors with the precious rag in his possession, hastens to have it duly protected by frame and glass, and then bedecks his surgery wall with the dear-bought toy. Oh! as he casts his eye upon it in after days, it should continually remind him of his wrongs and degradation—a member without privileges, a surgeon for ordinary emergencies—a professional leper having a name amongst the chosen people, but virtually excommunicated—"a goose," whose down and feathers must be plucked to make a warm nest for supercilious rulers. How passing strange that enlightened men should have so long submitted to such a galling bondage, and that there could be found rulers so much puffed up with the pride of office as to inflict the most outrageous evils upon those who are their brethren! The National Institute discovered no "mare's nest," when it announced to the world the perilous situation of nine-tenths of the profession, nor is the scheme Utopian which it proposes to adopt for their salvation. In the memorial which the president, vice presidents, and council recently addressed to her Majesty's Principal Secretary of State for the Home Department, there are uncited "burning truths" which will not fail to make an indelible impression upon the Government, and the class to which they especially relate. Here it is boldly stated, "that the general practitioners of medicine, surgery, and midwifery are without a head or home amongst the institutions of this country, and their position is, at present, most anomalous. That the College of Physicians, by its constitution and by-laws, can have no sympathy with them, but a direct interest in maintaining the class, in point of education, general and professional, and qualification to practise medicine, at as great a distance from the standard of that college as possible, and the College of Surgeons, since the recent grant of a charter, has no sympathy with them, but has a direct interest" to inflict the same injury as her beloved sister of Pall-mall—and that this College of Surgeons, moreover, "has rendered it totally impracticable for any great portion of them as general practitioners, although possessing its own diploma as surgeons, ever to become fellows of the col-

lege." Pretty colleges these! and a nice pickle the medical advisers of the labouring population of this country are in! Hear more:—"That though the general practitioners may now be estimated at many thousands, and have rapidly advanced in scientific and professional acquirements, and are possessed of great individual influence, *they are unknown in a collective capacity*; and legislative enactments have been attempted under the auspices of special institutions, representing particular sections of the profession, having interests peculiar to themselves, and diametrically opposed to those of the general practitioners, without even an allusion to their existence." And it is further said, that the constant efforts of the enemy are to depress the general practitioner in his attainments, his character, and his *status*. Who is there amongst the champions of corruption that can gainsay these things? or who amongst the thousands of the profession that will not humbly admit his present qualifications give him no collegiate respectability? The Institute, whose officers have just sent a memorial to the Government, a portion of which we have now quoted, will elevate its members to that position which gentlemen, scholars, and philanthropists deserve. Here there will be no fetters for the intellect, and no gags for the mouth, to prevent the free use of the mind, and the legitimate employment of the tongue. No playing at political leapfrog, where the members are compelled to bend low their backs that turncoat radicals, metropolitan hospital apprentices, and individuals of favoured families may take flying leaps over them to place and power: no; for as the doors will be opened to none but those who are duly qualified to enter, so those who have entered will be recognised as duly qualified to act. The present surgical diploma of membership is like the mark of Cain upon the possessor—making him, in a particular sense, a corporate vagabond: and the brand can only be effaced, and the calamities to which the individual is exposed averted, by the benign efforts of the newly-formed college.

And this is not all that it will do: raise the general practitioners as a body, to that respectable station which they ought to occupy; but it will give them that which will enable them to maintain it—*political force*. All experience tells us that it is not the numbers of an army which ensure the victory, but the compactness and discipline with which they are marshalled. Three hundred Spartans, at Thermopylæ, could resist, for three successive days, the most brave and courageous of the Persian forces, which, according to some historians, amounted to five millions; and, doubtless, that little band laid the foundation of the future greatness of the republics. Though we count ourselves by thousands, it will avail us nothing without an effective organization. The past has seen us divided and scattered: thus rendering ourselves so perfectly contemptible as to be "unknown in a collective capacity." Are we then to remain without the flame of honour and of patriotism burning brightly in our bosoms?—to be, like the unresisting sheep in the hands of the shearers, absolutely dumb? It is not enough that, having fought one battle and

brought the enemy to a stand, we should, barbarian like, disband our forces, and every man to his home; no, the crisis is not yet arrived which is to seal for ever our greatness or insignificance: for the question is not whether we retain our present situation, but whether we advance or retrograde. The Brodie phalanx is still in the field, armed to the teeth, and manœuvring to obtain such vantage-ground as shall ensure it a certain victory when the decisive action shall be fought. We have before observed, "that if ever there was a time when the organization of our body, commenced by the National Institute, should be energetically carried forward on one side, and warmly supported on the other, that moment is the present. We have our ranks to form and discipline, and we have a careful watch to keep over the movements of the enemy. Nothing but forcible and active measures on our side can prevent the question of Medical Reform from being settled in detail, away from us, and without our participation." To accomplish this, we have to show the Home Secretary that we are a people consolidated, determined, and energetic; a community of master-spirits, refusing to give that servile homage which supercilious corporate despots endeavour to exact; and satisfied with nothing less than the enjoyment of rights which justice must approve, laws which justice must enact, and a position which justice must accord. The beginning is with ourselves, which will afford a proof of our sincerity, and an earnest of our success.

One act of the profession in the hour of peril has been sufficient to teach us what union can do. The National Association was the offspring of necessity: it seemed to rush into existence with the same quickness, and the like perfections, as Minerva from the brain of Jupiter; and "the Great Unknown" averted impending destruction. It contained within itself, however, the elements of its own dissolution, but with this peculiarity, that from its ashes should arise an embodiment more glorious and substantial—the *National Institute*. Here the general practitioner gets what he wants—"a local habitation and a name;" here he can consolidate his strength, and treat upon the best terms with the Imperial Government for future privileges; here he has a college upon the "voluntary principle," which it will be for the honour and interest of the Executive to make a permanent incorporation; here, in a word, is a substantial reality which will answer of our respectability, concentrate our energies, and be the guardian of our rights. As we have said before, though young, it is in vigorous action:—suffering no opportunity to escape that may accomplish the ends for which it exists—appearing before the Minister with a power equal to old-established chartered institutions—and receiving the marks of respectful attention. "Well is it," we repeat, "that the profession could use the opportunity. Well is it that they can use it through the instrumentality of an organized body, which to the power of numbers adds the influence and respectability of responsible official position."

Having adverted to the benefits arising from the establishment of the Institute, the question

naturally arises, What are its prospects? Were it to receive according to its deserts, unmingled prosperity would mark its career; yet such seems to be the unfortunate condition of our nature, that we are always backward in according to excellence that which is its due. Never was there a philanthropist who has not suffered from the ungrateful opposition of a thoughtless multitude. From obliquity of the moral vision, the best motives have been mistaken, and the best efforts have been frustrated; and the consequence is, that while

"The good is oft interred with our bones,
The evil that men do lives after them."

It is too much for us to expect, then, that this new Institute will escape all the afflictions which have in times past assailed those who were truly great. There will be opposition to encounter from those who will shoot their arrows from a quiver hidden under the cloak of good intentions, as well as from open and undisguised enemies. A liberal college will make the corruptions of the old institutions more prominently repulsive; and injured reputation will goad on their abettors to revenge. All the strategy of war will be called into requisition by them, and, with the cruelty of cowardice, no quarter will be given. Justice, however, will maintain her own rights, and upon her standard will inscribe the inspiring and prophetic motto, "*Sub hoc signo vinces*."

Nor must it be forgotten that the Institute may have difficulties from the state of its treasury. Men's fingers become particularly sensitive when directed towards the pocket; and the button-hole which guards the sacred receptacle is stubbornly tenacious of its hold, unless omnipotent gold or silver demands admittance. This one thing is certain, however, that there is a wonderful sympathy between the heart and pocket; and when the former opens, the latter invariably yields to its influence. We know not, of course, how successful the Institute has been in pecuniary matters, but sincerely hope that a liberal profession will maintain its character in this particular department.

Let us not, while regarding the difficulties, forget there are great encouragements also. The cause is a good one: for it involves the honour, the happiness, the usefulness of the medical community. It seeks to provide for the general practitioner "an efficient control over the education of the members of the class to which he belongs, so that they may not only maintain the high standard of qualification which is now adopted, but that, by the cultivation of collateral sciences, they may promote the progressive improvement of the class, and thereby secure the true respectability of the great body of practitioners in this country, to whose skill and judgment the limbs and lives of the mass of the population are intrusted." And can so good a cause ever fail for want of support? Certainly not: for it carries with it the certain tokens of permanent stability. Respected by the profession, it will gradually secure its friendship,—by the Government, it will ultimately receive a charter of incorporation; while the existing colleges, compelled to profit by so good an example, will diligently "set their houses in order," lest a righteous judgment should be pronounced upon them.

ETHER.

Our office is literally inundated with details of new operations performed on patients under the influence of sulphuric ether. Operations would appear to have become the rule, rather than the exception, of surgery; and we had to await the present flood of communications to understand on one side the world's amount of surgical misery; on the other, how much that condemned small agent *ether* is destined to alleviate it!

Without troubling our readers with details of operations that have now no novelty to commend them to notice and which might fill our journal without imparting one iota of scientific knowledge not previously known, we will briefly note a few points which should be commended to especial notice, and investigation, in the further experiments which may be imposed on what has now been the usual routine of professional practice.

Are those erotic feelings which have been noticed, especially in females, and convulsive phenomena observed occasionally in both sexes, under the influence of ether, a physiological effect of that agent on certain temperaments, or a result of ether, either adulterated or misapplied? We know that ether, unless of a specific gravity of 730, contains alcohol. Now, if an apparatus be used which is heated to a temperature which will convert alcohol, as well as ether, into vapour, we have, in fact, a new process—alcohol is inhaled; and we have a condition approximating, if not identical, to drunkenness, in which are elicited phenomena like those induced by nitrous oxide. We have here obviously a very important point to be attended to; and it would appear of no little consequence that the apparatus used should, under this aspect, be constructed on the principle of Startin's inhaler, by which the application of heat may be carefully regulated.

Another question, which may not unreasonably be discussed, is "whether the ether, in producing insensibility, acts on the nervous tissues as a sedative, like opium, or exercises a direct influence on their structure and composition?" This is a subject of no small interest, and invites the experiments of the curious.

A third point, which may well be looked to in all future operations, is, whether the relaxation of the muscles, observed undoubtedly in many cases, is a concomitant of all? If the phenomena be producible at will, by means of ether, it is obvious that we have an important agency in the reduction of fractures, that must place ether's permanent establishment as one of the most valued appliances of surgery wholly beyond a doubt.

A fourth point, which is perhaps as important as any, is a faithful record of unsuccessful cases—or cases marked by unfavourable consequences. Hitherto our records have been Napoleonic bulletins—very ample on successes, very brief and taciturn on failures.

We add a further suggestion, and will leave the subject to another week. Have the uses of ether, *medically* as well as surgically, been essayed? What important services does it not suggest, with the modern apparatus, in asthma—and diseases generally of the lungs! Cases of this character would be really interesting as novel.

REVIEWS.

A Treatise on the Diseases of the Air Passage, Chronic Bronchitis, Laryngitis, Clergyman's Sore Throat, &c. &c. By HORACE GREEN, A.M., M.D., Vice-President of the New York Medical and Surgical Society. Wiley and Putnam, Waterloo-place, London.

The medical and the non-medical world have recently been thrown into a state of great excitement, in consequence of the suggestion of the inhalation of ether in surgical operations by our American brethren; and we have now to make known another transatlantic novelty, which we are sure will take many of our readers by surprise. Indeed we can readily imagine that many will be disposed to doubt the veracity of the author, so opposed to all commonly received opinions are the results with which he has furnished us in the work before us.

Dr. Green declares that during the last eight years he has treated upwards of 400 cases of diseases of the lining membrane of the larynx, by the direct application of a saturated solution of the nitrate of silver to that cavity! Now, when we remember what great irritation arises from the accidental introduction of any foreign substance beyond the epiglottis—when we know that a morsel of food, a single drop of tea, or even of pure water, entering this cavity, almost produces suffocation—we can scarcely conceive it possible that the passing of a sponge, saturated with this strong caustic solution, could be borne for a single moment; in fact, entertaining our former notion on the subject, we should fear that it would be attended with imminent risk to the life of the patient. Dr. Green acknowledges that when in 1840 he read a paper before the New York Medical and Surgical Society, giving the details of the treatment of fifteen cases by this novel method, such was the scepticism on the part of the society that they appointed a committee to investigate the matter; and, notwithstanding their previous incredulity, they made a favourable report. Aware of the suspicions likely to be excited by the announcement of his method of treatment, Dr. Green has seen fit to append the testimonials of Dr. Post, a distinguished surgeon connected with the New York Hospital, and other members of the profession, among whom we observe the name of Dr. Lee, the editor of the *New York Journal of Medicine*, all of whom corroborate the assertions of our author, and leave no room for doubt, that the practice which he recommends is not only unattended with danger, but, in many cases, is productive of the greatest benefit to the patient. Strange as it may appear, we doubt not that such of our readers who have been much engaged in surgical practice will, on reflection, recollect cases where, in introducing the tube of the stomach-pump, by mistake it has been passed into the trachea, and yet has excited but little irritation. Baron Larrey relates the cases of several who, by gunshot-wounds or other accidents, had lost the epiglottis, and who were under the necessity of receiving nourishment through a gum-elastic tube; and he declares that it was not unfrequently passed into the larynx without producing any annoyance. Mr. Ryland, in his work "On the Diseases of the Larynx," makes numerous observations which go to confirm the statements of our author; and those familiar with the writings of Desault are aware that he proposed that in cases of bronchotomy the elastic tube should be passed through the larynx into the trachea. We could cite other testimony on this point, but we must recommend those interested in this matter to peruse the work for themselves. Dr. Green has devoted several pages to the examination of the objections which may be offered us to the practicability of his method, and has given illustrations of the instruments which he employs. There are also several coloured plates, representing different affections of the pharynx, &c. &c. The position of the author, as vice-president of the New York Medical and Surgical Society, is a sufficient warrant of the respect in which he is held in that city, and is calculated to increase the confidence of those to whom he has been hitherto unknown.

We shall, doubtless, have occasion to refer to this

subject again; in the meantime we may safely assert that, whatever opinion may be formed as to the expediency of adopting this method of treatment by the direct application of these strong solutions of nitrate of silver, we must award to Dr. Green the credit of having done more towards the establishing of the practicability of the operation than any preceding writer. Although Troussseau and Belloz refer to the same proceeding, Dr. Green avers that, long before he had been made acquainted with their views, he had resorted to this proceeding, and that he was first indebted for the suggestion to a conversation which he had with the late Dr. Johnson, whilst on a visit to London in 1838. That distinguished physician, having spoken of the great prevalence of affections of the pharynx and larynx among public speakers in this metropolis, remarked, if the remedies could only be brought into contact with the parts affected, the efforts of the physician in these cases would be crowned with much greater success. On his return, Dr. Green lost no time in carrying out this hint, and the result has been, not only in his own practice, but in that of others, truly surprising.

ROYAL COLLEGE OF SURGEONS.—Gentlemen admitted members on Friday, Feb. 19:—H. Davies, T. Pratt, L. P. Madden, J. Nash, J. W. Poland, A. Gozybowski, A. Asmar, R. B. Power, E. L. Webb, and J. Hutchinson.

NAVAL APPOINTMENTS.—Surgeons: T. H. Keown, to the Marine Detachment at Port Easington; J. Caldwell, to Mariner.—Assistant-Surgeons: Dr. Wm. Smith, to Ocean; J. Lilburne (acting), to Belleisle; H. Gervais (acting), to Mariner; D. O. West, confirmed to Trafalgar.—Surgeon-Supt.: J. Lardner, to Asia, convict-ship; and R. G. Pashley, to Mariner.

At the late meeting of the Royal Society the minutes of the Physiological Committee were publicly read. In addition to many papers sent in and received, there was one announced as sent in, and rejected amid the general laughter of the learned audience—"Erasmus Wilson, on the growth and development of the epidermis."

Mr. Gale, an aeronaut, has constructed a balloon on an improved principle. All the gas which escapes by expansion, or otherwise, is collected in air-tight bags and attached to the middle of the balloon, and the car, grapnels, &c., are of improved construction.

MORTALITY TABLE.

For the Week ending Saturday, Feb. 20, 1847.

Causes of Death.	Total.	Average of 5 Winters.
ALL CAUSES.....	1253	1008
SPECIAL CAUSES...	1252	1001
Zymotic (or Epidemic, Endemic, and Contagious) Diseases.....	156	183
SPORADIC DISEASES.		
Dropsy, Cancer, and other Diseases of uncertain or variable Seat.....	100	112
Diseases of the Brain, Spinal Marrow, Nerves, and Senses.....	187	170
Diseases of the Lungs, and of the other Organs of Respiration.....	514	354
Diseases of the Heart and Blood-vessels.....	68	32
Diseases of the Stomach, Liver, and other organs of Digestion.....	77	70
Diseases of the Kidneys, &c.	14	8
Childbirth, Diseases of the Uterus, &c.	10	12
Rheumatism, Diseases of the Bones, Joints, &c. ...	3	7
Diseases of the Skin, Cellular Tissue, &c.	3	2
Old Age.....	78	81
Violence, Privation, Cold, and Intemperance.....	31	30

No. 388. SUMMARY. MARCH 6.

MORTALITY TABLE 48

LECTURES ON SELECT POINTS OF SURGERY.

By WILLIAM FERGUSSON, Esq., F.R.S.E..

Professor of Surgery in King's College, London; Surgeon to King's College Hospital, &c.

ON CLEFT PALATE, AND ON STAPHYLOPORATHY.

Author's experience increased since the reading of his paper on these subjects in 1844, before the Medical and Chirurgical Society of London; nature of cleft palate; different forms and kinds of; its complication with harelip; effects of malformation on deglutition and on voice and speech; method of obviating defects before modern operation of staphyloporathy; advantages and disadvantages of latter proceeding; indifferent success of the operation, although performed by most of the leading surgeons in Europe and America; success of Roux, Mutter, and Dr. J. M. Warren; apathy of British surgeons on the subject; author's investigations; anatomy and physiology of cleft palate first described by him; new operation proposed and performed by author, and its success in various instances; reviews of different proposals, by Roux, Bushe, Dieffenbach, Pancoast, Liston, Mittleur, and J. M. Warren; fit cases for operation; age proper for its performance; author's operation described; ligatures and knots; new knot; after treatment; causes of failure of operation; examples of success of author's plan; effects of operation on voice and speech, &c.

Two years have now elapsed since I delivered a special lecture on these subjects, and about the same time I communicated a paper to the Royal Medical and Chirurgical Society, which was afterwards honoured with a place in the volume of "Transactions" for the year 1846. During the interval my experience has accumulated, and I am now desirous of stating the results, while, at the same time, I bring before my pupils as much upon such topics as pertains to the duties of the chair which I occupy in this college.

The state of the mouth, familiarly known under the name of cleft palate, is congenital, although a condition somewhat analogous to it occasionally results from injury or disease. It is chiefly to the natural malformation that the following observations apply, although they are suitable in many respects to other imperfections in the palate and roof of the mouth generally. The congenital defect is met with in a variety of forms: in some instances the fissure is limited to the uvula, when that part appears double; in others the fissure extends further forward, so as to leave the velum in two halves; the whole, or a portion only of this part, may be thus; the fissure may extend partially or entirely through the hard palate; the alveolar ridge may also be implicated, in which case the condition is usually, if not always, accompanied with fissure in the upper lip as well. The harelip and cleft palate very frequently go together, although it is by no means unusual to see either the one or the other by itself. The fissure in the uvula and

soft palate is invariably in the mesial line; even in the hard palate it appears to be so, although commonly the vomer is attached below, directly in the middle, and the fissure communicates with one nostril only. When the alveoli are divided also, the fissure is always to the side, and thus is particularly conspicuous when there is a double harelip present at the same time. There is, then, an intermaxillary bone immediately underneath the columna, on which rests the middle portion of the upper lip. Sometimes the fissure appears as a narrow slit, and in other instances is so wide and large as to cause the mouth and nostril to appear like one huge cavity.

The effects of cleft palate are observable in various ways. In infancy, if the malformation be at all extensive, there may be imperfect nourishment, in consequence of part of the food passing into the nostrils during deglutition; and in advanced years the peculiar tone of voice and defective pronunciation are remarkably characteristic of this condition. Infants sometimes die from inanition in this state; and in the adult the deficiencies alluded to are often such as to mar his prospects in life. The tone of the voice often gives rise to unjust suspicions against the sufferer, and there are many so conscious of the unpleasant sound that they use it as little as possible.

Until the present century, the means known for obviating the defects alluded to were of a very imperfect kind. In the adult, the opening could be closed only by an obturator or false palate; and in the child, even now, we know of no other remedy for the defect than a spoon or bottle, with some contrivance attached to it whereby the food is passed almost into the pharynx at once. In modern times, however, something more has been done for the adult; and it has been proposed to treat the fissure in the palate on the same principles as have long guided us in cases of harelip. Roux and Gracé in Europe, and Warren in America, pared the edges of the cleft, and brought them into contact in such a manner as to permit union by the first intention; and so the malformation was soon remedied, as in the more familiar example of harelip.

The intention with which an obturator or false palate is applied is, that, by closing the direct communication between the mouth and nostrils, the sound of the voice may pass outwards through the mouth without the nasal accompaniment which gives its unpleasant character. It is also used to prevent the escape of food upwards; for although the adult, by long custom and constant care, can generally swallow all his food and drink, yet, in an unguarded moment, a lapse may occur, and cause much an-

noyance. The objects of the operation being the same as those just alluded to, it will be very apparent that, if the two sides of the palate can be brought together to have the same effects as the obturator, the advantages are great in favour of such a proceeding. If the operation be successful the parts are put in a condition similar, in most respects, to their natural state, as if no such malformation had ever been present. As regards the voice and articulation, this was remarkably evinced in the case of the first patient on whom Roux operated. When the gentleman, a student of medicine, returned among his former friends, there was such a change for the better that he could not have been recognised by his speech alone.

Notwithstanding the apparent merits of the surgical operation for cleft palate (staphyloporathy, as it is called), there are certain disadvantages connected with it which should always be borne in mind when an opinion is required on the propriety of performing an operation, or the probability of its results. Even with the utmost care the proceeding when done may end in partial or complete failure. There may be some portion of the fissure, perhaps in the hard palate, which may baffle the surgeon's skill; or, from causes over which he has no control, the union of the soft parts, which it is his object to effect, may not occur. Even under the most favourable circumstances, as regards union, the patient's speech may not be so much improved as had been anticipated. Then there are difficulties connected with the operation so vexatious, so trying to the surgeon's patience, as well as to the endurance of the patient himself, that it must always be looked upon as one of the most harassing that we are ever called upon to perform. The slightest opposition on the part of the patient may prevent the operation being performed; and a trifling indiscretion, in not attending to the junctions of the surgeon afterwards, may mar the effect of the proceeding, however successfully it may have been accomplished at the time. All these circumstances, as observed in different cases, have, no doubt, had effect on the surgeon's mind, and as the successful results have not been commensurate with the seeming disadvantages, have rendered him somewhat careless regarding the proceeding.

The operation has, nevertheless, been done by most of the leading surgeons of the day, among whom may be mentioned Roux, Gracé, the Warrens—father and son, Dieffenbach, Brodie, Guthrie, Liston, Bushe, Cusack, Crampton, Mittleur (of Virginia), Mutter, and Pancoast (of Philadelphia), &c. In 1842 it was said that Roux had performed it upwards of one hundred times. In two-thirds of the simple cases, and in one-third of those

which were complicated, the proceeding had been beneficial. In 1843, my friend Dr. Mütter had operated twenty-one times upon the soft and hard palate, and out of this number "had failed to relieve the patient but in two cases"; and Dr. J. Mason Warren had been equally successful in thirteen out of fourteen instances, in which he had operated. Indeed the success of these gentlemen had seemingly been greater than that of the distinguished author of the operation—Roux, although it would be observed that the cases were far fewer in number than had been treated by that surgeon. Few though they are, however, comparatively, I do not suppose that any surgeon in this country has operated on so many; no statistics have been drawn; no one has had the courage to publish an account of his cases; and a general impression has prevailed that the proceeding has been very unsatisfactory. Among the various cases that had come under my own notice, until within a comparatively recent date, the constant failures had been such as to induce great apathy on my part towards the proceeding—an apathy which had been somewhat increased by the failure of an operation performed on a gentleman in London, by Roux himself, when here on a visit a few years ago; and also by a similar result following an operation done by Mr. Bowman upon whose hands the proceeding had received a cry justice. I mention the latter case thus pointedly, because I shall have to draw attention to it again in a future part of this lecture.

I had not, however, given up all interest in cases of this malformation, and certain circumstances induced me, about three years ago, to bestow more attention and study on the subject than I had done previously. A preparation of cleft palate in my possession gave me an opportunity of investigating the anatomy, and this led me to draw certain conclusions regarding the physiology and surgery of these parts, such as I believe had never been made before.

It had long been familiar to those accustomed to see such cases on the living body, that during deglutition the two portions of the uvula came together in the middle line; but no one had attempted to explain how this could happen, and even such an acute observer as M. Malaigne (a) stated, that it was "by a muscular action, of which it is difficult to give an explanation." The dissection of the parts enabled me to explain this in a way which I imagine is incontrovertible; and to show you how this happened, as well as for other purposes, it will now be best that I should explain to you the condition of the parts in this malformation, and contrast it in as far as may be requisite with the natural state.

The preparation now before you exhibits the upper part of the mouth and pharynx of an aged female subject. The muscles of the pharynx have been carefully dissected, as have also those connected specially with the palate. A glance at the roof of the mouth shows the gap in the mesial line, and how the uvula, soft palate, and a portion of the hard, are involved in the defect. Behind it may be observed that the constrictors are not so broad,—so capacious, as in the natural condition, but that the muscular fibres are nevertheless as strongly developed. The upper border of the superior constrictor is especially well marked, and here it may be seen to form a kind of semicircular margin, extending between the basilar process of the occipital bone and the internal pterygoid plate, on which margin the levator palati muscle seems to rest. A perpendicular incision has been made through the pharynx behind, exactly in the mesial line, and the mucous membrane having been stripped off the inside, the muscularity is thus rendered still more distinct. The mucous covering has also been taken off the upper surface of the palate, whereby one side of the nostril immediately above, and the muscles of the palate have been more extensively exposed.

It may now be seen how the two portions of the uvula and corresponding parts of the soft palate touch each other during deglutition, for it is evident that, as the superior constrictor muscles act, they must throw or push the soft tissues in front forwards and inwards;—an effect which will be aided by the superior fibres of the middle constrictors, which, stretching across as they do from one side to the other, having no attachment mesially, as is also the case with the lower fibres of the superior muscles, must contribute powerfully to the result in question. A remarkable difference may here be observed between this and the normal state of the parts: the palato-pharyngeal muscles are not attached to each other, as in the well-formed palate. These muscles are seen to form the principal part of the free margin of the palate along the line of fissure; their course is somewhat irregular from their upper end to their lower, anxiety being towards the middle; and it is that during action, if not opposed in any way, they must pull the parts outwards—an effect the reverse of that described by Diondi, Muller, and others, as belonging to the muscles in their natural condition. The levator palati is throughout its entire course, and the constrictor may as be clearly seen out. The levator, it will be perceived, pulls the parts outwards, by pulling it, not only acts very efficiently the movable portion of the palate, but its sphere of action, from the muscle being clearly muscular throughout its entire course, is so great that, during rigid contraction, it must forcibly pull the soft parts upwards, backwards, and outwards. It is worthy of special observation, that the tensor or circumflexus palati has but very little influence on the volume, ton, pull as I choose upon it, there is only the slightest movement to be observed at the parts where its tendon spreads on the surface of the soft palate. Neither in the natural nor in the cleft palate can this muscle have a power at all to compare with the levator, which, from its length, position, and character generally, is the principal motor of this very mobile part. The anterior pillar of the fauces is very slight, and the fibres of the palato-glossus are indistinct; the posterior pillar, however, is distinct enough, and formed as in the natural state by the bundle of fibres of the palato-pharyngeus. The *aygos uvulae* is by no means distinct; a bundle of fibres, about the size of a crowquill, may be seen on the lower part of each free margin of the soft palate.

From such an inspection as this preparation afforded, I was led to take those views of the physiology and surgery of the parts, the explanation of which forms the principal object of this lecture. It required no great foresight to perceive that the movement of each side of the palate must depend chiefly upon the action of the levator muscle and palato-pharyngeus. The influence of the levator muscle might have been calculated on from previous knowledge, but that of the palato-pharyngeus could scarcely have been thought of. Both must evidently have the effect of widening the fissure, especially the levator; and the various conditions under which the palate may be seen can be explained by reference to these two muscles. When the mouth is looked into, and the soft portions of the palate are in a quiescent state, the fissure will then appear probably in a medium state. A slight irritation, with a probe or point of the finger, will cause a corresponding movement—the soft parts will be drawn upwards and outwards, so that the gap will be enlarged. If the irritation be increased, the same parts will be so acted on that they will almost disappear on the sides of the fissure, but even now, if an effort at deglutition be made, the two portions of the uvula will be forced together, by the action of the superior constrictors, as already explained. It seemed to me that under ordinary circumstances, after the operation for closing the fissure, the slightest irritation would be likely to call the levators and palato-pharyngeal into action, and so induce that dragging on the stitches with which surgeons were

so familiar—an influence sufficient, in some instances, to cause ulceration in the seat of the threads, or, in others, to cause separation of the recently-united parts. I therefore supposed that, if these muscles could be divided before bringing the edges of the palate together, the parts would remain so quiet immediately afterwards that there would be greater probability of union in the mesial line taking place than if the muscles were left entire or untouched. It was not long before I had an opportunity of testing the project on the living body. The result was so satisfactory that I tried it in another instance shortly afterwards, and here the effect was most complete. The two cases were appended to my paper on this subject when laid before the Royal Medico-Chirurgical Society (a), and since that date I have operated on eight more, making ten in all, in eight of which I have been perfectly successful in closing the soft palate. In some of these there has been fissure of the hard palate as well, and the parties have been content with the remaining comparatively small apertures, or have had them closed by obturators. I know of four other instances where the operation, conducted the plan recommended by me, has been successful, and a fifth which failed. During the same period I have known three examples of failure by the ordinary method. Thus, out of fifteen cases on my plan, there have been three which did not succeed, while all those done in accordance with Roux's operation were failures.

A COURSE OF LECTURES ON CLINICAL MEDICINE.

delivered in the Theatre of Queen's College, Birmingham, by SAMUEL WRIGHT, M.D.

Lecturer on Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham; Physician to the General Dispensary; Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

quinta de la herida—complaint of 1846, meaning of the term *sequela*, illustrations, injury to the knee, and relations thereof to the stomach; the converse, injury to the knee followed by peritonitis; concussion from a fall, illustrations of it, *sequela* of the bowel complaint of 1846, as they applied to children, anasarca, two varieties of it, one from simple debility, the other from congestion of the kidneys, relative treatment of them, observations upon particular remedies; ascites, a *sequela* of the bowel complaint, varieties of it, pathology; treatment; post-mortem appearances, intestinal flatulence a *sequela*, localization of it; observations thereon; treatment, mesenteric disease; observations upon, treatment.

GENTLEMEN.—We have now to speak of the *sequela* of the bowel complaint of last year, and of their treatment. The term *sequela* is applied to any form of ailment which succeeds to another, as its consequence. Some diseases are particularly liable to *sequela*. Thus, smallpox is apt to be followed by gastro-intestinal irritation, by bronchitis, or bronchorrhoea; measles by ophthalmia, and scarlet fever by anasarca. These secondary diseases are not necessary consequences of the preceding, for smallpox, measles, and scarlet fever, often enough occur without leaving any morbid succession; and what are sometimes their *sequela*, at other times appear as primary and unconnected affections. Still these things frequently relate to each other as cause and effect. Observation has given us the fact, and pathology its explanation. It is to pathology that we owe the distinction between *sequela* proper, and those that are only *apparently* such. You must not infer that because one ailment comes shortly after another, it comes as a consequence properly so called; it may come quite accidentally. A man accustomed to very

active habits, and much out-door exercise, falls upon a slide and breaks his leg; the fracture is a simple one, but it confines him to his bed, and, after a fortnight's stay therein, he loses his appetite, and becomes dyspeptic. There is nothing surprising in this. Had he, without having broken his leg, shut himself up in his bedroom for mere fancy, and never breathed the fresh air for a fortnight, it is more than probable that the sudden change would have considerably disturbed his digestive function. Suppose, again, that his arm, instead of his leg, had been broken, and that his accustomed recreation had been little suspended, the chances are that his stomach would have suffered in only a mild degree, perhaps not at all. Could we then say, that in the first instance the dyspepsia was directly consequent upon the fractured leg? I think we should rather say that it was the result of confinement, and other sudden change of habit. We know of no morbid sympathy which would be likely to obtain between the gastro-intestinal function, and such a fracture as I have spoken of, except what might be the natural consequence of altered living, or of sympathetic fever; therefore the dyspepsia would not deserve to be called a *sequela* of the injury.

The man, however, instead of breaking his leg in the fall, sprains his knee very seriously; his tongue becomes furred, and his appetite is gone in twenty-four hours; perhaps he has epigastric tenderness, and frequent itching. Is this stomach trouble a *sequela* of the sprain? I should say so. And why? Because it has occurred too soon to be accounted for on the score of confinement, &c.; because we know that a severe injury to a large joint like the knee, with its complicated ligamentous structures, and its ample synovial membrane prone to inflammatory action, is more serious than a simple fracture of the arm or leg; and because experience tells us that injuries of this joint are apt to be followed by sympathetic disturbance of the stomach. This fact is familiar to our observation - it is one of the unexplained truths of pathology; but it is still a truth, for it has numberless attestations. Moreover, it is variously corroborated. Not only will injury to the knee-joint directly produce gastric disorder, but, if this occur even casually in a chronic case of knee disorder or disease, it will effectually retard the progress of cure. Primary dyspepsia, again, is not an infrequent occasion of mischief, simple or serious, in the articulation I allude to. I have more than once directed your attention to anomalous pains of the knees, successive of dyspepsia, in cases that have come before us; in one, in particular, there was an approach even to synovitis. None of these had the character of rheumatism, commonly so called, and they all subsided as the gastric function improved.

Suppose, again, that this fall and injury to the knee-joint, instead of being followed by disorder of the stomach, was followed by pericarditis, would this properly be a *sequela*? It would certainly deserve to be called so, if the pericarditis had nothing more directly to account for it than the injury to the knee. In this case there would be both a physiological and a pathological reason for the inference. We know the relation which holds between the ligamentous structures of the large articulations, their synovial membranes, their secretion, and the fibro-serous investment of the heart and its secretion. We know them to be so allied in nature and function that, *a priori*, we should say they would be as likely to sympathise as distant mucous membranes. And we know this, also, from pathological experience. We see articular rheumatism connect itself with pericarditis much oftener than does muscular rheumatism; and a subacute form of pericardial inflammation is not an anomaly as a sequence of injury to the knee-joint.

This fall, however, instead of fracturing any bone, or spraining any joint in particular, might have shaken the individual excessively: what would be the likely result? We know how mental emotions of joy or grief will paralyse and prostrate the nervous system; death, instan-

taneously or slowly, has often followed a sudden shock produced through the mind. And why may not a sudden concussion produced by a fall have a fatal termination? It frequently has, especially in old people. A severe shake of this sort in advanced life is not uncommonly succeeded by gradual sinking, without the least effort of nature to rally. We sometimes see robust people injured thus. I am at this time attending a dispensary patient, a female, thirty-five years of age, who, three weeks ago, tripped upon a slide, and fell with great violence upon the lower part of her back. The fall so shook her that she was unable to stir until helped by a policeman, who conveyed her home. At the time of her accident she was in good health; for two or three days, subsequently, she felt excessively sore all over; this, however, passed away, leaving her in a state of great prostration, as she still continues. Her appetite is impaired, she sleeps indifferently, and she has lost nearly twenty pounds in weight: the *mamme* in particular, which were previously ample, firm, and round, have wasted and shrivelled until there is scarcely any left. No organ in particular seems to suffer, but the nervous power appears to have sunk through the shock. This sinking is a *sequela* of the concussion produced by the fall.

Instead of the depression, however, the general soreness first complained of might have extended itself to rheumatism. I have lately attended a case of this kind in consultation with Mr. Wood. A lady, in her usual health, fell down a whole flight of stairs. She was not stunned, but excessively shaken. Within twenty-four hours she was the subject of general rheumatism of a very urgent kind, which was only relieved by very prompt and active treatment. In its subsidence it left the heart irritable and intermittent in its action, with occasional violent palpitation, but without any evidence of inflammatory process, or of structural change. In this case there was a succession of *sequela* the morbid action of the heart was a sequence of the rheumatism, and this of the fall.

Sometimes *sequela* do not make their appearance until after the cessation of the more manifest symptoms of the diseases of which they are successive. This generally happened with the ailments which were consequent upon the bowel complaints of last year. We will first speak of them as they appeared in children.

In these subjects a common *sequela* was anasarca. I saw many examples of this, but there appeared to be only two distinct varieties. In one, though the quantity of water passed every twenty-four hours was less than natural, yet it was not conspicuously so; the secretion rarely being more than one-third deficient. This urine was sometimes clouded with mucus, but it never contained albumen, or the colouring matter of the blood: it was passed freely, and without any evidence of straining or pain; there was no tenderness on pressure over the kidneys, nor any sudden twitching of the legs whilst this pressure was being made, or at any other time. The children had an emaciated, emaciated look, lost their appetite and flesh, and some of them had profuse night sweats. These, however, did not relieve the anasarca condition, which gradually increased, unless efficient remedies were given; and the sufferers at last died, some apparently from exhaustion, and others from serous effusion in the cranial, thoracic, or abdominal cavity. In these cases the anasarca seemed to be the offspring of laxity of tissue and impoverishment of blood—the consequence of the excessive drain from the bowels, and the debilitating effects of it. There were no morbid appearances arrived, except a striking bloodlessness of the facial organs, and local accumulations of transparent, almost colourless, serum. These states of debility, and these terminations thereof, you sometimes meet with in the impoverishment of chlorotic subjects; after severe mercurialization of leuco-phlegmatic people; and especially after large losses of blood, either by the lancet or during parturition.

These cases were only successfully treated on

a tonic plan. Good milk, beef-tea, sago, arrow-root, stale bread, and, if the child were old enough, small quantities of finely-chopped mutton, and occasional small doses of wine and water, were amongst the best materials of nutriment. Fresh air, whenever the weather permitted, early bed, and sponging with tepid salt water, were serviceable adjuncts. The medicinal treatment of most use, when the bowels were not irritable, were occasional doses of sulphate of quinine, with tincture of bark, and some cordial, such as tincture of cardamom, or ginger. With weak stomachs, quinine alone will often not agree, and it is advisable to give, in conjunction, some stimulant which will prevent its producing coldness, flatulence, or pain. Some stomachs, however, cannot bear cold liquids, whatever they may be. It is useless to give a quinine mixture in such cases, unless you order each dose to be slightly warmed. I have often done this without at all deteriorating the operation of the tonic, and with the desirable advantage of enabling it to sit easily and without inconvenience on the stomach.

When the bowels were irritable, tender on pressure, and disturbed with flatulence, a vegetable tonic, such as gentian, calumba, or cascarilla, with soda or ammonia, was of great service. Nitric ether was conveniently added to this or to the other form of mixture, whenever a sluggish state of the kidneys suggested its administration.

Occasionally, a small dose of grey powder proved useful by aiding absorption; but great care was required for its exhibition, for when the prostration was severe, any form of mercurial was dangerous.

In the other variety of anasarca, the kidneys were clearly implicated. The urine was always considerably less in quantity than natural; sometimes the secretion was almost entirely arrested. It was rarely deficient in albumen, and often contained this in considerable quantity. Not rarely blood globules were distinctly visible in the urine; and again, it had a tawny hue, derived from the colouring matter of the blood, such as you not unfrequently see in certain forms of typhus fever. Micturition was slow, difficult, or painful; there was tenderness on pressure over the kidneys; and the little patients, who could describe their suffering, complained of shooting pains down the thighs.

These cases were difficult to treat, and too generally proved fatal. Besides the anasarca, or local serous effusion, in which they corresponded with those above mentioned, there was always found more or less congestion of the kidneys, which not only accounted for the deficiency of their action, but for the abnormal character of their produce.

In these instances, the best treatment consisted of local depletion, by leeches or cupping, over the kidneys, followed by sustained counter-irritation. Additionally, salines with excess of alkali (potash the preferable), and mild diuretics, such as nitric ether, nitrate or acetate of potash, were of frequent service. If the renal secretion improved in quantity and quality, its restoration was the signal for tonic treatment; and such cases generally did well. If, however, local depletion and diuretics produced little effect, the patient rapidly became worse, and died without affording any prospect of recovery.

Ascites, again, was an occasional *sequela* of the bowel complaint of 1846. In one or two instances I had reason to suspect, from tenderness and fulness in the right hypochondriac region, that some structural alteration of the liver, probably congestion, was the cause: but, not having had an opportunity of verifying this from *post-mortem* aspects, I am not able to speak confidently.

In other cases, perhaps the more numerous, the abdominal dropsy was evidently the result of subacute peritoneal inflammation. The origin of this, it is difficult precisely to account for; but it may have arisen sympathetically with the irritated and inflamed state of the mucous membrane of the intestines, the probability of which we learn from what we know occasionally

to result from the operation of drastic purgatives; it may also have occurred as a consequence of exhaustion, for we know that states of vital depression are apt to be terminated by peritoneal inflammation. Whatever the cause, at least we know that there was, not unfrequently, sub-acute peritonitis, and that this was followed by abdominal effusion. There were tension and tenderness of the abdomen; a quick, somewhat hard pulse; sickness and subsequent retching, flatulence, and faintness; and, if these were not remedied, soon fatal sinking and death.

In either example the cases were difficult of treatment. The amount of bleeding that would have been necessary to produce any good effect was quite inconsistent with the strength and health of the patients. Purgatives, again, were inadmissible, not only because they might restore the bowel complaint, but because there was no direct indication for their use. Hydriodate of potash ointment, constituted of one drachm of the salt to one ounce of spermaceti cerate, was ordered to be rubbed over the hypochondriac region in those cases in which the liver appeared to be deranged. At the same time, vegetable tonics, with alkalis and hydriodate of potash, were occasionally administered internally, and less often alternative doses of grey powder or blue-pill; but it was seldom that any evident good was the result of this treatment. The abdominal dropsy gradually increased, the skin became yellow, and the patient sunk.

When the a-cites was the result of subacute peritoneal inflammation, counter-irritation, and that mild, was the only local treatment that was practicable. If active remedies were used the patient threatened to sink before them; and, if remedies were abandoned, the case seemed to be utterly hopeless—and where was our choice?

There were many instances of recovery during treatment, but I am not prepared to say that nature was not curative—there were many instances of death during treatment, and I am not satisfied that even our best means in any degree averted or arrested the fatal issue.

In the unfortunate cases there was found a variable amount of fluid in the abdominal cavity; sometimes clear, and, again, turbid and flaky. The mesenteric veins were congested; the peritoneum thickened, in some places coated with lymph, and in others loosely adherent to the adjoining viscera.

In other instances, intestinal flatulence was the particular *sequela* of the bowel complaint. Usually this was general; that is, on percussing over the abdomen, the tympanitic sound was heard pretty equally everywhere, and, on pressing and attempting to grasp the bowels, their distention seemed to be uniform. Occasionally, however, there were strange local accumulations of air, here and there, giving very much the appearance of a circumscribed tumour. It was very resistant, bounded, and, on a superficial examination, might easily have been mistaken for a substantial swelling. On percussing this spot, the sound was purely tympanitic, and hence there could be no doubt of the nature of the local enlargement. I am not able to account for the anomaly of a diffusible gaseous fluid being thus confined in a particular part of an extensive and permeable cavity, but it is not a very uncommon pathological feature amongst dyspeptics, who suffer from intestinal flatulence. They will tell you of swellings in this place, and that, of the abdomen, and call them tumours, and on careful examination you find these said swellings to be nothing but wind.

In the cases I speak of, friction to the surface of the abdomen had often an excellent effect in dissipating the flatus; again, the same end was answered by local stimulation, by a mustard poultice or turpentine, over the tympanitic part, and again, by the administration of an osmotic enema. This rarely failed to be effective. It is a remedy of most excellent service in such cases, and their like, and I confidently recommend it to your adoption. You will often find an osmotic enema produce a dislodgement of flatus from the colon, and even from the smaller

intestines, after carminatives and purgatives given by the mouth have failed to be of service.

Tonic carminatives were also beneficial. In young subjects, appropriate doses of aromatic confection, carbonate of ammonia, or sal volatile, with peppermint-water, and, if there were much pain, with syrup of poppies or tincture of opium, were useful remedies. In older patients, the place of peppermint-water was well filled by some tonic vehicle, such as calumba, gentian, cascarrilla, or cusparia. Your *materia medica* has taught you the relative properties of these, and you will anticipate the cases in which they would be respectively serviceable.

Gentle aperients of the unirritating class were necessary, and I found none better than castor oil. When not using this, I gave colocynth pill, with its equivalent of soap to moderate its action.

Mesenteric disease was another *sequela*, amongst children, of the bowel complaint of 1846. It was chiefly characterized by an increase, often rapid, of the size of the abdomen. In some instances parents deceived themselves with the idea that the child was getting fat. On pressing the abdominal surface, however, well-defined masses of hardness were felt here and there, which clearly told that the enlargement was not due to fatty deposit. On percussing over these several spots a dull flat sound was elicited, which showed there was no accumulation of flatus; and as there was no fluctuation whatever, fluid in the cavity of the abdomen had no share in its augmented magnitude. These masses of hardness might have been *scybala* in the intestine; but the previous purging, and the present absence of all symptoms of intestinal accumulation, were strong evidences against the probability of such a thing. Moreover, the masses felt to be more superficially seated—in fact, were more easily recognised by the touch than are *scybala*; and, more than all, there was that peculiar physiognomy—the anxious, haggard, old look, and the dingy, yellow complexion, which are so constantly remarkable in the mesenteric disease of children.

These cases never improved or recovered. Strangely enough, they were rarely accompanied by even looseness of the bowels; and we know that even mesenteric disease in general is attended by a most intractable purging. Perhaps the sensibility of the bowels had been so weakened by the previous irritation and discharge that it was not affected by the altered condition of the mesenteric glands. The sufferers gradually wasted and shrivelled, except in the abdomen, which generally continued to enlarge, and at last died, apparently from exhaustion. The nervous vigour appeared to have received a shock from which it never rallied; and upon this, as its consequence, came a cachectic state, and the effects of both were fatal.

Tonic treatment, medicinal and alimentary, with counter-irritation with iodine, was tried, but without avail. The sufferers fared alike, whether well or ill attended. In some cases the mesenteric glands were found simply enlarged and indurated; in others, they contained a cheesy-looking scrofulous matter; and in others, again, a similar deposit was scattered over the peritoneum.

DUMAS ON ORGANIC CHEMISTRY. No. XIII.

ON THE URINE.
(Continued from p. 7.)

We have already stated that fresh urine, in its normal state, invariably possesses an acid reaction. M. Berzelius affirmed that this property of reddening litmus-paper was owing to the presence of a certain quantity of free lactic acid. Latterly, this opinion has been somewhat shaken by the following experiments due to M. Liebig.

If fresh human urine is saturated by baryta, we have a precipitate thrown down; and, by

taking the precaution of not exceeding the point of saturation, we shall find no trace of baryta in the filtered liquid. Calcined or carbonate of magnesia will present a similar action. Now, if the urine owed its acidity to lactic acid, we ought to find in it a lactate of baryta or magnesia (which are soluble in water), and these bases would be revealed under the action of reagents,—a circumstance which does not take place. But, as the urine contains alkaline phosphates, and as baryta and magnesia form insoluble salts with phosphoric acid, the neutral lactates, produced during the neutralization of the urine, might have been converted into alkaline lactates, in which case there would have remained neither baryta nor magnesia in solution. To resolve this problem, we must then have recourse to a direct experiment.

M. Liebig admits that putrefaction does not destroy lactic acid; therefore, if this acid exists in fresh urine, we ought, according to this chemist, to find it in putrefied urine; and, if we cannot succeed in demonstrating its existence in the latter liquid, we must conclude, not only that it does not exist in fresh urine, but that this fluid contains no substance likely to aid in its formation. It is very possible, however, that the lactic acid may disappear in the midst of so complicated a fermentation as is that of the urine.

Let us now, however, describe the process adopted by M. Liebig, for discovering lactic acid in putrefied urine.

The urine is evaporated to dryness, at first over the naked fire, then in a water-bath; the residue treated by a mixture of alcohol and sulphuric acid, and then saturated by oxide of lead. The precipitate is separated by filtration, and the filtered liquor decomposed by a current of sulphuretted hydrogen. The solution, separated from the sulphuret of lead, is evaporated to dryness in a water-bath and treated by alcohol, which precipitates the chloride of sodium. To remove the remaining soda, we must dissolve oxalic acid in the alcoholic solution while hot, and, after having separated the oxalate of soda, saturate the liquor by oxide of lead. The clear solution is again precipitated by sulphuretted hydrogen, concentrated in a water-bath, and mixed with an excess of subacetate of lead; we have thus formed an abundant white precipitate, which is to be separated from the liquor by filtration. The limpid solution resulting from this treatment should contain lactic acid.

The lead, which is present, is finally precipitated by sulphuretted hydrogen. The liquor, after partial evaporation in a water-bath, is subjected to ebullition with hydrate of baryta, and a large quantity of ammonia thus driven off. After the decomposition of the ammoniacal salt, the barytic compound is carefully decomposed by sulphate of zinc. Every conceivable plan for extracting from this liquor crystals of lactate of zinc has been adopted; but, hitherto, these attempts have been totally unsuccessful.

M. Liebig has also employed other means for procuring lactic acid from the urine, but all his experiments have given a negative result. He has, however, constantly been able to prove the presence of some organic acid, but this he found to be acetic acid mixed with a highly azotized, brown, resinoid matter. Proust has also confirmed this fact.

M. Liebig affirms that the acidity of fresh urine is owing to the presence of hippuric and uric acids. The following is the method which he adopts for isolating hippuric acid:—Fresh urine is evaporated to a syrupy consistence; the residue acidulated with a little hydrochloric acid, and then agitated with its volume of ether to facilitate the separation of the ether, we should add to it a twentieth part of alcohol. The hippuric acid will be found dissolved in this mixture, which also contains a little urea. On agitating it with water, this liquid attracts the urea and the alcohol; the ether, when removed with care, furnishes by evaporation crystals of hippuric acid.

M. Liebig admits that hippuric and uric acids are found in a state of solution with the phos-

phates of soda and potash contained in the blood, and which pass thence into the urine. The disappearance of the alkaline reaction of these salts in the last-named liquid must, therefore, be owing to the presence of the above organic acids, and perhaps, also, to a certain quantity of sulphuric acid, arising from the combustion of the sulphuretted materials of the organism. This manner of viewing the constitution of urine led M. Liebig to manufacture an artificial kind. By dissolving 90 grains of phosphate of soda, P_2O_5 2 Na O + 24 aq., in a pint of water, he

obtained a solution which possessed an alkaline reaction. On adding 15 grains of uric acid and a like quantity of hippuric acid, and then applying a temperature equal to that of the human body, viz., 37° or 38° C., the two acids were dissolved. A few hours after cooling, he observed a deposit of uric acid containing soda: it greatly resembled the uric acid which is, after the lapse of some time, thrown down in the urine. The deposit, collected twenty-four hours afterwards, weighed but $7\frac{1}{2}$ grains. The dilute mineral acids produced a precipitate in the filtered liquor.

The foregoing considerations necessarily lead us to inquire the condition in which the uric acid itself is found in the urine. MM. Cap and Henri affirmed that it was combined with lactic acid. M. Pelouze has since proved that lactate of uric acid does not exist. Some observers have imagined that the uric acid might be combined with uric acid. MM. Cap and Henri admit the existence of this combination in the urine of birds and of reptiles. In that of the herbivorous mammifera, the uric acid, according to the same chemists, is found partly in the state of hippurate of uric acid. But the existence of all these salts is at the least doubtful, and I am more inclined to believe that the uric acid is present in a state of liberty; still, as we know that this principle may combine itself with sal ammoniac and chloride of sodium, we should perhaps admit the existence of these combinations in the urine, to a greater or less extent.

The alterations which the urine undergoes, when left to itself, are not very difficult of solution. M. Gay-Lussac has proved that the access of oxygen is necessary for putrefaction to manifest itself in this fluid. When preserved from contact with the air, in well stoppered bottles, it loses neither its transparency, its acidity, nor its odour, and throws down but a very slight quantity of uric acid. But, so soon as the access of oxygen is allowed, this gas is absorbed and gives rise to a true fermentation.

It may be, that by its combination with the azotized extractive matters contained in the urine, and perhaps also with the colouring matter (as is the opinion of M. Liebig) the oxygen transforms these substances into azotized ferments which are precipitated in an insoluble state. Under the influence of these combinations, the uric acid is rapidly transformed into carbonate of ammonia by fixing the elements of water. The urine becomes strongly alkaline and produces a lively effervescence when treated by acids. The surface of the liquid is covered with a white pellicle, sometimes of a perfectly mouldy character, and at the same time small crystals of the ammoniac-magnesian phosphate are deposited on the sides of the vessel. The uric acid is partly thrown down, while the hippuric is transformed into benzoic acid. Such is, according to Dr. Ure, the origin of this body, which was discovered in the urine by Scheele and Proust. This last-named chemist, a long time since, pointed out the presence of acetic acid in putrefied urine. His observation has been confirmed by M. Thénard, and more recently by Liebig; but we do not know the origin of this acid.

To form a complete chemical history of the urine, we must now regard it in another point of view. Like all animal secretions, that of the urine is subject to certain variations, according to the conditions in which the organism is placed. After laying down a few general principles upon the urinary secretion, considered in a chemical

point of view, we must then endeavour to trace the conditions which are capable of modifying it. As one safe step in this study, we will first cite some analyses of normal urine, made by MM. F. Simon and Lehmann.

The following is M. Simon's analysis of the urine of a man, thirty-three years of age, of a sanguineous temperament, but whose digestion and general appearance were not very good:—

	1.	2.
Density	1.011	1.012
Water	933.76	956.00
Urea	12.46	14.58
Uric acid	0.52	0.71
Alcoholic extract and free lactic acid	5.10	4.80
Spirituuous extract	2.60	5.59
Aqueous extract and mucus	1.00	
Lactate of ammonia	1.03	2.55
Sal-ammoniac	0.41	
Chloride of sodium	5.20	7.28
Sulphate of potass	3.00	3.51
Phosphate of soda	2.41	2.33
Phosphate of lime and magnesia	0.58	0.65
Silica	trace	trace
Solid residue	36.80	44.00

OTHER ANALYSES OF THE URINE OF THE SAME INDIVIDUAL.	The urine of the morning.—He had drunk a little water through the night.		After drinking a glass of water and of coffee.—He was for two hours in a state of general excitation, so that the pulse beat 100 per minute.		Urine collected half an hour after the foregoing.
	ACID.	LESS ACID than the first.	VERY ACID.		
Density	1.010	1.008	1.014		
Water	972.60	980.00	957.60		
Urea	8.40	7.57	15.26		
Uric acid					
Extractive matters	13.96	8.62	19.11		
Ammoniacal salts					
Chlorides					
Phosphate of soda	1.85	1.25	2.75		
Sulphate of soda	2.97	2.20	5.00		
Phosphate of lime and magnesia	0.48	0.26	0.65		
Solid residue	27.66	19.00	43.40		

These different analyses suffice to show how variable is the proportion of uric acid contained in the urine of the same individual, according to the circumstances attending its production. Indeed, we can scarcely hope to arrive at a satisfactory knowledge of the principles of the urine, unless we adopt the precaution of operating on the whole of the fluid collected during a space of twenty-four hours, and then taking the mean composition, as compared one day with another. The following analyses have been made by M. Lehmann, on separate quantities of urine voided during the day:—

	1.	2.	3.
Water	933.76	931.41	932.41
Urea	31.45	32.91	32.90
Uric acid	1.02	1.07	1.07
Lactic acid	1.49	1.55	1.51
Aqueous extract	1.62	0.59	0.63
Alcoholic and aqueous extract	10.06	9.81	10.87
Lactate of ammonia	1.89	1.96	1.73
Chlorides of sodium and ammonia	3.64	3.60	3.71
Alkaline sulphates	7.31	7.29	7.32
Phosphate of soda	3.76	3.66	3.98
Phosphates of lime and magnesia	1.13	1.18	1.10
Mucus	0.11	0.10	0.11
SOLID MATTERS	63.24	68.58	67.59

Physiologists had supposed or admitted from the earliest times, that the kidneys wholly elab-

orated the urine and the soluble organic matters which are found in it. M. Prevost and myself have, however, demonstrated that urea—the most abundant principle of the urine—exists in the blood after the extirpation of the kidneys, and that the functions of these organs are consequently confined to eliminating this principle, without aiding in its formation. The same may probably be said with regard to the uric acid and the other organic and inorganic principles of the urine.

Kidneys are found in all the superior classes of animals; but urea does not invariably constitute the most abundant principle which these organs are charged with secreting; in birds, serpents, &c., almost the whole of the urine is composed of uric acid—a product which exists in the human urine in but very small quantity. However this may be, the azotized principles, in all the superior classes of animals, constitute the most abundant and the best defined organic materials of the urine. In considering the composition of those different bodies, one is struck, at first sight, with the large quantity of azote which they contain; and, if we bear in mind that the excreting organs are, in general terms, destined for freeing the economy of those materials of the organism which have become unfit for the purposes of life, we are naturally led to the following conclusion:—that the function of the kidneys consists in collecting and eliminating the urea or uric acid arising from the metamorphosis of our tissues, or from the excess of aliments introduced into the system. Add to this, that the urine also bears off all the soluble inorganic salts, of which the organism requires to be freed, and we shall at once perceive the full importance of the functions which the kidneys are destined to fulfil.

There is a beautiful system of mutual dependency in the animal economy. The functions by which life is manifested are never accomplished singly, but are combined one with another in the most intimate manner. And, perhaps, one of the best exemplifications of this harmonious action of our organs is found in the relations which exist between the functions of the kidneys and those of the lung. The oxygen of the arterial blood, passing into the capillaries, there destroys, by a true combustion, the tissues which have become unfit for life: while the carbon and hydrogen of these tissues tend, at least in part, to transform themselves into carbonic acid and water, ultimately to be rejected by the lungs. But what becomes of the nitrogen? The most simple combination which it could form would be that of ammonia; but, as this body cannot exist in a state of liberty in the economy, nature causes it to undergo some modification; for this purpose it has merely to be brought into contact with carbonic acid, and, by eliminating from this combination the elements of water, it is transformed into urea. This principle, being inert and soluble in water, can pass without the least danger through the current of the circulation, and be eliminated or rejected by the kidneys. Such is the origin of urea in the economy. We see that it is, in some sort, a product of combustion, arising from the oxidation of the azotized matters of the system.

The relation between the urinary secretion and the phenomena of respiration has been experimentally proved. We may also readily perceive this dependency by a glance at the following table, in which we have placed in apposition the mean quantity of urea secreted in twenty-four hours, and that of carbon burned in one hour, calculated, in each case, upon individuals nearly of the same age:—

	Urea excreted in 24 hours.	Carbon burned in one hour.
Child, eight years of age	13.5	5 grammes.
Adult male	28.1	11
Adult female	19.1	6.3
Old man	8.1	7.4

We may here state, that for the respiration to have burned, without danger to the economy, 11 grammes of carbon in the hour, it necessarily follows that the alimentation must have been

more abundant than in those cases where the quantity of carbon consumed merely amounted to a granule, and consequently that the production of urea must have been increased. But, from what we have already said, it is easy to understand that all those circumstances which excite a greater or less degree of activity in the respiration must at the same time modify the urinary secretion.

M.M. Simon and Lehmann have found, by direct experiments, that, after violent exercise, the quantity of urea increases in the urine; this may, perhaps, be dependent on the copious perspiration which will have augmented its relative quantity, for everything which favours the circulation and the respiration tends to reduce the absolute proportion of the urea. Uric acid, which is richer in carbon than urea, will be formed in preference when, in consequence of a less active respiration, the matters burned by the arterial blood undergo an imperfect oxidation. We know that persons attacked with gout, or with calculous affections, lead in general a sedentary kind of life—one very likely to favour the formation of uric acid.

On the other hand, it has been remarked that, as a consequence of fatigue and over-exercise, the urine may become alkaline. We can readily explain this fact, by bearing in mind that uric acid is capable of being transformed into urea, when subjected to the action of an excess of oxygen, and that hippuric acid itself may undergo an analogous oxidation. As a consequence of these principles disappearing, or being formed in less quantity, we find that the urine must necessarily lose that acid reaction which is due to their presence alone.

Proust has shown that the ingestion of fatty aliments (which introduce an excess of carbon into the system) causes the urine to become thick and to give a deposit of minute crystals of uric acid. All these facts prove the remarkable influence which the respiration exercises over the urinary secretion.

carry on the circulation. Letting this flap hang down over the nose, he drew together with strong ligatures the sides of the great wound he had made in the forehead; and I was surprised to remark how nearly they approximated. He afterwards told me he had ceased to make incisions under the hair on the temples, in order to diminish the tension of the parts and to allow the lips of the wound to come into closer contact, according to the method recommended by Celsus; since doing so caused much greater irritation to the system, and retarded recovery, while it did not proportionally ameliorate the appearance of the scar.

Lint was placed in the wound, and tightly secured by sticking-plaster. An incision was now made along the ridge of the nose connected with the left side of the long neck of the flap, which had much contracted in its dimensions, and curled inwards, as I think Petit, Hill (of Dumfries), John Bell, and others, have remarked the scalp to do when removed. The parts having been well washed with water, all bleeding ceased, and all coagulated blood removed, the flap was turned round, its long neck fitted into the groove prepared for it on the ridge of the nose, and its broad part adjusted so as to replace the absent ala, to whose cut margins it was securely attached by needles and ligatures. The man left the theatre with his appearance much improved, having a well-shaped and perfect, though much enlarged, nose.

Dieffenbach's great experience has taught him that transplanted parts always shrink after union with the surrounding parts has been accomplished; and hence it is necessary, in these operations, not only to make the flap of a size much larger than will eventually be required, but also to calculate with nicety its probable diminution. I carefully watched this case; for the first few hours the nose was dressed with pledgets soaked in cold water, after which it was freely exposed, without dressing or covering of any sort. About twenty-four needles and ligatures kept the new organ *in situ*, and at the end of eight days so perfect was the union that all these had been withdrawn. Dieffenbach told me I had witnessed one of his best cases; and truly the improved appearance of the man assured me that few could be better. I did not witness the termination of the case, but, so soon as the wound on the forehead had entirely healed, the twist and the connecting neck that had been introduced between the eyebrows and along the ridge of the nose would be removed, the edges of the wound brought together with a few needles, and the cure completed. No sensation was retained in the transplanted part, and Dieffenbach said it would be several months before it would be re-established; and its tardy return will be easily understood when we reflect that sensation every where depends on certain nervous filaments, called sensitive, extending between the part in question and the sensorium, and that these filaments are necessarily cut through in the operation; nor is it until they have become connected with other nervous trunks proceeding to the sensorium that sensation is re-established. A transplanted part is thus for some time in the condition of the greater number of the organs of the body, living by virtue of its ganglionic nerves alone, while few or no sensitive nerves extend from it to the sensorium.

I witnessed two other operations for improving the appearance of the nose—one where a crooked organ was made straight; the other where deformity of the ridge was remedied—with remarkable success. But, as these methods are described in Dieffenbach's work, I need not enlarge upon them here. I shall merely observe that in all rhino-plastic operations the surgeon should be in no hurry to complete them, and be remarkably careful not to attempt the union of parts until all bleeding has ceased, and lymph begun to exude from the cut surfaces; otherwise the blood, which is poured out both from the flap and the prepared grooves, will act as a foreign body between them, and retard or altogether prevent union; in the same way as in a fractured

bone, the blood effused is an obstacle which must be removed before bony union can take place.

I will here relate a very interesting case, which I witnessed. A young lady had travelled from the south of England to consult Dieffenbach. Some years before she had had fever; which, as often happens, had been followed by glandular swelling of the neck. A surgeon, most unwisely meddling, had opened it; no matter, however, found exit, and the wound, healing by granulation, had left a deep and very ugly sulcus on the inner margin of the sterno-cleido-mastoid muscle. It was a hole more than an inch long, and fully a quarter of an inch deep and wide; its base was strongly attached by a fine skin to the jugular vein, which was plainly distinguished, blue, beneath it. Dieffenbach enclosed the whole scar or hole within two semilunar incisions, meeting at each extremity; and then, with a very fine scalpel and small hook, he entirely removed the cicatrix. It was a most delicate operation—indeed, it was as removing and preparing for demonstration upon a living subject a coat of the jugular vein—so intimate were the attachments. The dissection occupied nearly five minutes, great care being necessary, since the slightest indiscretion might have wounded the vein, and entirely prevented a successful result. It was nearly a quarter of an hour after the dissection that Dieffenbach brought the edges of the wound together. He waited till all bleeding had ceased, and assured himself that no blood was left in the wound. Then its sides were brought accurately together, and secured by six fine pins, such as are used in entomological cabinets to transfix insects. The wound was covered by a pledget of lint kept constantly wet with cold water. On the third day three needles were removed, and on the 6th the last was taken away, their places being supplied by sticking-plaster. I saw this young lady five weeks after the operation; the frightful hole in the neck was no longer there, and in its place was merely the unpuckered cicatrix of a simple incised wound healed by the first intention. In six or eight months all redness will probably disappear, and the scar be scarcely perceptible.

I now proceed to describe one of the most dreadful deformities that can be imagined, and I wish I could tell the tale in the same graphic manner as Dieffenbach told it to me.

"It was late one evening," said he, "that three strangers requested to see me—a man and two women; and one of whom, who was closely veiled, wished to speak to me, as I was informed, alone. Her companions having retired, she seemed to cast her eyes around the room to ascertain that no one else was present; and then, with some hesitation, and without uttering a word, she slowly raised the thick black veil by which her face and head had been concealed, and a great portion of her person enveloped.

"I had seen much in my life," continued he, "that was shocking; and, as I thought, the most hideous deformities of face and figure were so familiar to me that I could behold them comparatively unmoved; but here I started back, shuddering and horror-struck. A death's head, a skull with glistening eyes, red and everted eyelids, and a skeleton face, stood involuntarily grinning before me. The cheeks and lips were absent, and in their place a thin red skin covered scantily the almost denuded bones. In place of a nose was a large triangular hole, through which, when she gave utterance to sounds—speak she could not—the tongue protruded, for the palate bones were gone, and the oesophagus was freely exposed to view. At the upper portion of this dreadful orifice, through which three fingers could be introduced, a red and bony process protruded, extending upwards between the remains of eyebrows, while its lower margin was the remains of the upper jaw, now reduced to a small and toothless bony rim. Where cheeks had been, red and indurated cicatrices crossed each other in all directions, and, as I have said, ectropium existed to a great degree. This is no exaggerated portrait of a young girl of eighteen

DR. BUSHNAN'S VISIT TO DIEFFENBACH. PLASTIC OPERATIONS.

LETTER II.

[To the Editor of the Medical Times]

[Continued from p. 229, Vol. XV.]

SIR,—It was Dieffenbach's plastic operations that first gained for him a European reputation. In these operations, which truly require for their successful results not only a peculiar talent, but the most practised eye and the most expert hand, his volume on the subject had declared him to stand alone as the great master and most successful operator; and, since my translation of this had brought him more before the English profession, I was glad to hear that there were two or three cases in the Klinik for operation; and, when I had witnessed one of these, I was convinced that the celebrity of Dieffenbach in these cases was well merited, and his adroitness far from overrated. I will shortly relate a case, and then proceed to a few details of one of the most extraordinary and remarkable plastic operations that has ever yet been attempted.

A man, about forty years of age, was introduced to the theatre. The left ala of his nose was entirely wanting, and a ragged surface extended round the margin of the cheek, the nasal bone, and septum; the columna was unimpaired. With one stroke of the scalpel, the edges of the sore were entirely removed and a groove formed in the cheek. Dieffenbach then roughly formed in sticking-plaster the shape of the absent ala—much larger, however, than that of the right side—and applying it to the forehead, he dissected from it a similar piece of skin, leaving a long narrow slip or connecting tongue between the eyebrows to the nose to

says of age; member of a noble and powerful family, but nevertheless the victim of scrofula. I stood late at night and alone with this dreadful apparition—a foul thing, which forcibly reminded me of the prophet of Ephraim, when he raised his veil. Instead of a human voice, hissing and unintelligible sounds proceeded from the cavity in the face; and I drew back with horror, as she advanced to place her finger on my nose. Well did I understand the appeal, and deeply did I regret my inability to ameliorate the condition of this unfortunate lady. When I had made her understand by signs—for she spoke but Polish, which I did not understand—that I could do nothing for her, an exciting scene followed; she cast herself before me in a state of the deepest mental agony, imploring by signs my assistance; and when I summoned her companions, one her brother, the other her governess, to assist in calming her, she hastily resumed her veil; for, for years she had not allowed her family to behold her deformity. The governess spoke French, and I told her I could do nothing but recommend a mask; and then I hastily withdrew from this strange midnight scene, the recollection of which will never be effaced from my mind.

"The next day I left Berlin for Vienna; and scarcely had I arrived there, than the wretched lady again presented herself to me. She had heard of my departure, and had immediately followed me. Here I called in the assistance of the great dentist Carabelli, with whose aid I succeeded in procuring a set of teeth, and a false palate which facilitated eating, and made her speech more intelligible.

"The more I considered this case," continued Dieffenbach, "the more convinced I felt that I could do nothing further; and that it was utterly impossible to obtain a nose, or even a fleshy covering for the hole in the face. The bones of the forehead were nearly naked, and the thin, spare, and cicatrized skin of the temples was not sufficient for the purpose. A casual examination of the arm, however, showed much lobes and thin skin, and as I raised a fold of it between my fingers, and pressed it into the form of a nose, the idea struck me that I might transplant a portion of it to a spot near the inner edge of the right eyebrow, where the skin was not so much destroyed, and afterwards remove it by degrees in the same manner as heavy monuments are sometimes slowly transplanted from one place to another."

Dieffenbach acted upon this idea, and proceeded to relate to me the steps of the operation, or rather series of operations, which extended over a period of eighteen months, exhibiting as much the skill and perseverance of the operator as the patience and confidence of the unhappy lady. I am very unwilling to lengthen this letter by describing the operations; but since, in the letters which are to follow, I shall not recur to plastic operations, I may briefly state, that a nose was formed from the skin of the upper part of the left arm, and that in a very novel manner. A triangular piece was marked out, about a third larger than the supposed size of the required nose; an incision was then made along its sides and upon the outer and inner thirds of its base. By subcutaneous dissection, this triangular portion of skin was separated from the muscle, but still left attached to the arm by its somewhat broad apex, and the middle third of its base. The edges of the wound on the arm were then brought as much together as possible by straps; and the sides of the triangular portion of skin turned inwards and properly secured. It was three months before the parts had healed, and then Dieffenbach had obtained what may be called a triangular loop of flesh attached by its base and apex to the arm. This was to form the new nose. The parts being healed, Dieffenbach proceeded to fix the prepared nose to the inner edge of the right eyebrow, which, as I have said, was thick and puffy; this he did in the old Taliacotian method, by detaching the apex of the new nose, or triangular portion of cicatrized skin, from the arm, uniting it *in situ* with the brow, and fixing it by sutures and appropriate bandages.

He told me he had many doubts as to the success of the operation; and the great advantage of this mode of operating is, that if we do at first fail in attaching the new nose to the forehead, we may commence *de novo*, at any time we may heal the wound we have made on the brow, and again attempt to attach to it the stump which still remains upon the arm. Again, it is preferable to the common Taliacotian operation, where, even if successful, the patient's face is deluged with the results of suppuration, as is not the case in that performed by Dieffenbach. But to return to the case before us: contrary to expectation, the stump did unite to the brow; in a few days all ligatures were removed; the patient bore the disagreeable position of her arm with the greatest fortitude, and could with difficulty be persuaded at the end of a fortnight to allow the base of the triangle to be cut away, and the arm released from the face. But I will, in this place, no longer follow the case—it was perfectly successful; and suffice it to say, that by transplantations, frequent and repeated small incisions, and parings, and graftings, and by the introduction of tubes and needles, and by compresses, a respectable nose was at length formed, by appropriate operations the cicatrized portion of both eyes was relieved, the many and hard cicatrices were removed from the face, and at the end of eighteen months the patient was presented to the Klinik, a very different being to what she was when I first saw her; and she quitted Berlin with the consciousness that, by her steadfast and enduring perseverance, she had compelled the professor to an operation he had deemed impossible, and even by the success of which he had been amply rewarded. I am, &c. &c.

J. SERRVSSON, BISHOP, M.D.,

Fellow of the Royal College of Physicians of Edinburgh.

Wiesbaden, Duchy of Nassau.

(To be continued.)

REMARKS ON THE CLIMATE OF LOWER EGYPT, PARTICULARLY ALEXANDRIA, AND THE PLAGUE THAT APPEARED THERE IN 1815, 1810, AND 1811. ILLUSTRATED BY OFFICIAL RETURNS FOR TEN YEARS.

By WILLIAM THOMPSON KAY, Esq., Assistant-Surgeon of the Plymouth Division of Royal Marines.

Extent.—The portion of the north-eastern part of Africa embraced in this paper extends from 31° 14' to 29° 50' north latitude, and from 23° 50' to 31° east longitude.

Physical Characters.—Lower Egypt is an extensive and fertile plain, well supplied with water by the numerous subdivided branches of the Nile, and by the countless canals that intersect it. The cultivated soil of this district consists exclusively of the rich alluvium (a) deposited by the Nile after its annual inundation. The Nile, being swollen by the rains of Abyssinia and interior Africa, commences at the summer solstice to rise, until it attains its greatest height (b) about, or soon after, the autumnal

(a) This was analysed by Regnault, and found to contain in 100 parts—

Water	11
Alumina	48
Carbon	9
Carbonate of lime	18
Carbonate of magnesia	4
Oxide of iron	6
Silex	4

(b) The height to which it rises varies: at Thebes it is about 36 feet; at the cataracts, 40 feet; and at Rosetta only 3½ feet. In 1843 it rose at Cairo to the height of 26½ feet; a good Nile being considered to be 25 feet. From time immemorial the first day of the rise of the Nile has ensued soon after the summer solstice, and at Cairo the phenomenon has usually taken place some time between the 1st and 10th of July; in 1843, however, there was a rise of the river on

equinox; and, after remaining at its maximum for about the space of four days, it gradually falls. The alluvial deposit takes place during the period the waters remain stationary; this earth is brought down by the river in its course through Nubia and Upper Egypt, superimposed upon the substratum of the primordial sands, annually increasing, and spontaneously diffusing, by means of filtration, its fertilizing powers to a considerable depth in the soil.

Lower Egypt possesses the largest number of equatorial plants, which must be attributed to the waters of the Nile bringing from the south many seeds which here propagate themselves. The most common are the carob-tree, the olive, myrtle, lentisk, tamarisk, caper-plant, pomegranate, citron, banana, sycamore, fig, several species of mimosa, and the cactus opuntia. At Cairo may be seen in some of the gardens the weeping willow, cypress, white and black poplar, ca. in arborea, tamarind, and our common elm, which here only attains the height of a shrub. At Memphis I observed the doum (crucifera Thebaica), and the date; and on the banks of the Nile is still to be found the cyprus papyrus of Linnaeus, or *papyrus* of the Greeks, from which, in former times, the Egyptians formed their paper, afterwards rubbing it with the oil of the cedar, to preserve incorruptible the archives of the kingdom. The fumed lotus (blue and white), Egyptian onion, citharus tinctorius, the sacred onion, the bean, the oleander, and acacia Nilotica, are to be found in most of the cultivated soil of this district, many of them forming important articles of commerce.

Alexandria, once the splendid capital of Egypt, and one of the most celebrated cities in the world when governed by the Ptolemies, lies in latitude 31° 13' N. and in 29° 55' E. east longitude from Greenwich. It is situated on the shores of the Mediterranean, between the Lake Marcotis and the harbor formed by the Isle of Pharos, about twelve miles west of the canopic branch of the Nile.

The climate of Alexandria, so extolled by the ancients for its salubrity, and particularly by Strabo and Josephus, has now become extremely unhealthy. The constant exhalations from the damp salt soil, and the presence of sulphuretted hydrogen gas in the atmosphere during the winter months, develop many diseases, particularly catarrh, malignant fever, rheumatism, dysentery, and ophthalmia. The atmosphere is literally saturated with saline moisture, which is evinced by the clothes, boots, woollen articles, &c., of those who reside there: the hygrometer also affords direct evidence of it (a), and the walls of the houses are covered with saline particles. The Lake Marcotis, which is nearly fifty miles long and twenty in its extreme breadth, has been converted into a salt marsh since the 13th of April, 1801, when the English army made a canal, by which the sea was admitted from the Lake of Abou-Keer, and the evaporation from it materially contributes towards keeping up this moist state of the atmosphere and generating malaria. The constant humidity which prevails in Lower Egypt arises, no doubt, from its

the night of the 5th of May, which continued four days (destroying in the gardens of Ibrahim Pacha, at Rhodda, 30,000 trees, plants, and shrubs), after which the water fell, and continued doing so until the period of the summer solstice. History affords no example of so early a rise of the river, and only a few instances are recorded of a second rise taking place shortly after the first: one of these occurred in the reign of Cleopatra, and the other in the year 1737.

(a) Ali Bey, who resided here between the 12th of May and the 30th of October, 1806, says, "During my residence the sea breeze reigned continually; the air was nearly always full of moisture, and the hygrometer marked a very high degree of moisture on the days when the greatest heat ought to have been felt."—Vol. 1., p. 331. See also table given at the end of this paper.

vicinity to the sea, and the low nature of the soil, which, as in the above case, is swampy. Iron speedily becomes oxidized when exposed to its influence, and polished steel, firearms, and surgical instruments, soon get rusty, and silver tarnished. This state of the atmosphere decreases, however, as we advance towards the tropic. It acquires its maximum intensity during the overflow of the Nile, and dews.

The plague was unknown in ancient Egypt during a long series of centuries; but since the sixth century of the Christian era, the practice of embalming the dead has been discontinued, chiefly on account of St. Anthony, who died 356, preaching against this ancient custom. The embalming was discontinued, and in the year 543 Egypt was ravaged by the first plague, which, spreading over Europe, devastated it for half a century.

Before the month of July, 1834, Egypt had been exempted from the plague for many years. Between 1831 and July, 1834, the plague appeared several times at the lazaretto of Alex-

andria, and its appearance in July, 1834, has been attributed to various causes; but it is generally believed to have been imported by prohibited articles being disembarked after vessels had brought them from places infected with it. This was the origin of the epidemic of 1835, which continued with unabated violence until the 22nd of September, 1837, and from this date to the 6th of April, 1838, i. e., about six months and a half (the longest interval without plague in the town of Alexandria during the decennial period, given in Table II.), it was not seen at all. It returned, however, with increased force during the six hot months of 1838, and again very slightly, about the same time in 1839, after a new interruption. The recurrence of it in 1840 continued with greater force in 1841.

The institution of an administration of the public health took place at Alexandria at the termination of 1831, after the invasion of the cholera; and I here subjoin two tables formed from their registration books.

The population of Alexandria, before the plague of 1835, was 60,000, and consisted of:—

Arabs	20,000	Armenians, Cops,	
Turks	6,000	and Jews	4,000
Negroes	4,000	Europeans	5,000
Moors		Workmen in the Arsenal	6,000

Seamen	12,000
Soldiers	3,000

During the French expedition in 1798, it was only 6,000; while at present it is estimated at upwards of 60,000.

The houses are generally built of white calcareous stone, covered with plaster made of lime, chopped straw, sand, and salt earth, and have all flat roofs, covered with cement; some of them have the foundation walls of stone, and the superstructure of bricks taken almost entirely from the ruins of the ancient city. The *huts*, which are on an average eight feet square, are of the most miserable description, being composed of mud, the floors lower than the ground outside, seldom having even an apology for a window, and the door a mere hole, sufficient to allow the owners to pass in and out.

The streets are narrow, irregularly built, dirty, and dark, from the projecting windows of wooden lattice-work, which overhang and almost cover them in, in many parts of the city.

Drainage is not thought of, and it is a very common thing to observe pools of stagnant water filled with decomposed vegetable matter and the putrid carcasses of animals.

The food of the poor people consists chiefly of beans, peas (boiled in brackish water), olives, water-melons, and a coarse black bread. The meat sold in the markets is unfit for food, sometimes half putrid.

The water was formerly conveyed to Alexandria by means of a canal, that was filled by the overflowing of the Nile, which river it joins at a short distance from Rahmahieh, and is fourteen leagues in length, in a straight line; but the canal was cut through by order of El-Bey, near Dumanhour; and the city has now no other than the briny water of some wells, or that which is brought by sea in boats. (a) This was written by Ali Bey in 1806, and still continues the same.

Temperature.—There is one remarkable character in the temperature of Egypt, which is, the transition from day to night. The thermometer, which was high at sunset, generally falls eight or twelve degrees during the night, so that the nights are seldom, if ever, oppressive. The mean temperature in the shade (b) throughout the year, in the afternoon, is as follows:—

January	57°	May	83°
February	63°	June	92°
March	66°	July	95°
April	72°	August	96°
		September	84°
		October	76°
		November	68°
		December	65°

The prevailing winds are the hot southerly winds, which occasionally last for three days together, and extend over a period of somewhat more or less than fifty days, commencing in April, and lasting throughout May; they are dreadfully oppressive, even to the natives. It is these winds that bring the malaria from the Mareotic district, and cause the plague, which is always most severe during the period of their visitation. The scorching "seemoom, (c)" and the oppres-

Total	237	938	7,425	119	75	94	34	154	75	29	12,262

(1) The mortality during these two months is mixed with that of the plague, which was epidemic at that period.

(2) The registration of the mortality was suspended during the months of June and July, those of August and October comprise only cases of cholera.

(3) Includes 40 cases of cholera.

(4) Includes 1 case of cholera.

(5) Includes 126 cases of cholera.

(6) Includes 28 cases of cholera.

The year 1835 did not present such a great difference from the mortality of those following, because they succeeded the epidemic of the plague of 1831. The months where the mortality is considerably less are those of March and June. The minimum of the eight years for March is 272; that of April 274; that of May for nine years is 981 8-9th; and that of June for eight years is 327 4-8th.

The most unhealthy months are those of September to December; the minimum of eight years for September is 434; that of October is 590 2-8th; that of November for nine years is 533; and that of December for the same is 470 2-8th. The minimum of October is considerably more than double that of March.

The months of March and October form the extremes of the ascending and descending scale of periodicity of the mortality at Alexandria.

The Epidemic of 1835.—The month of May of the eight following years is shown to be the most favourable for the development of the plague; September, October, November, December, and January, are the months in which the fewest number of cases occurred. The minimum of cases for those months, since 1837, was 134.

It is worthy of remark, that in the months of September to January, where the plague decreases and terminates altogether, there is a corresponding and considerable augmentation in the mortality of those not attacked with this disease, as seen in Table I.

give "khamseen" seldom last more than a quarter of an hour or twenty minutes, and proceed from the S.E. and S.S.E., bringing with them clouds of impalpable dust and sand, and swarms of mosquitoes, fleas, &c. They occur in the spring and greater part of the summer. During June it blows from the N. and N.E., and continues in July to blow from the N., varying from the N.W. to N.E. Towards the end of July and part of September, it blows from the N. strong in the day and calm at night, and towards the end of September the wind comes from the E.

Fogs occur sometimes in winter, and are so dense that it is scarcely possible to distinguish objects at a short distance. They only last a short time.

Dew.—The dew is rare in winter, but very abundant in summer, in Lower Egypt, during the west and north winds which bring the evaporation of the waters of the Mediterranean. They disappear with the south winds.

Rain.—It is generally believed in England that it never rains in Egypt, and the error has probably arisen from modern travellers who have visited the country during the dry season. It rains little in Lower Egypt, but at times, severe storms of thunder, lightning, and rain occur. The number of days on which rain falls is from twelve to sixteen days throughout the year, being the average of upwards of forty years. The rains commence generally in October, and continue in November and December, terminating in March; during this time there is often a week without any rain, and at others it lasts much longer than a week. In 1824 it rained so violently for eight days that it caused many houses to fall in, and ruin of all kinds; rain is extremely rare in Upper Egypt, and appears at long intervals.

Hail is rare in Lower but more common in Upper Egypt; during eight years there was an abundant fall of hail, some of the hailstones being the size of a large hazel-nut. In the different falls which succeeded to this long interval, and in 1828 at Abouzabel, the hailstones were very large, resembling small nuts. To this may be attributed in a great measure the ruin of the campaign, as they hurt several individuals, and killed many animals.

Snow is very rare in Lower Egypt. When in 1833 snow fell at Alexandria, at Rosetta, and extended to Atfeh, the old people of the country, on being asked, declared they never recollected such an occurrence before.

The atmosphere generally is characterized by an excessive clearness and transparency, giving a beauty to the sun as it rises and sets that render

prostration, ophthalmia, cephalalgia, apoplexy, and dysentery occur."—Clot Bey's "Egypt," vol. i., p. 17.

it easy to imagine the poetical enthusiasm of the Arab effusions respecting them; and the nights are most beautifully serene.

Dust.—When the moisture produced by the inundation and dews cease, the soil is dried rapidly, and the surface becomes covered with impalpable dust, which is so fine that it penetrates everywhere, giving rise to an Egyptian proverb, that it will penetrate the shell of an egg. This obstructs the pores of the skin, is inspired, and lodges in the bronchii, giving rise to a series of distressing maladies.

Alexandrian Districts.—The most unhealthy quarter is the Ras-el-tin. The soil here is calcareous, barren, and covered with filth of every description—vegetable and animal—in a putrid state, exhaling a fetid odour that is speedily detected on approaching the village. Covering an area of nearly four furlongs and a half, are between 700 and 800 mud huts, which contain upwards of 10,000 inhabitants. Adjoining this spot is a cemetery, where the bodies, half exposed to the sun, produce the vile fetor that is observed on approach.

The market district, which is situated between the Custom-house and the Frank portion of the city, is also a hotbed for malarial, the streets being very narrow, dirty in the extreme, dark, and fetid.

The Turkish district is the most healthy; but even here filth is allowed to accumulate, and would, were it not for the dogs—the scavengers of the city—be productive of much mischief.

It is not surprising, then, that in certain seasons and years, malaria should be generated in the town, and cause such serious epidemics as those of 1835, 1840, and 1841, for, although measures are taken to prevent the introduction of the plague, yet no means are adopted by which the city may be purified, or to render the most populous parts less susceptible of the generation of aerial poison.

Causes of the Plague.—The causes of the plague of 1835, 1840, and 1841, may be ascribed, I think, without any doubt:—1st, to the filthy state of the villages, more especially that of Ras-el-tin; 2nd, to the decomposition of vegetable and animal substances during the hot weather; 3rd, to the badly constructed huts, the floors being lower than the ground outside, no windows, the door insufficient for free ventilation, and the atmosphere within warm and moist. 4th, to crowding many individuals on too small a space; 5th, to the use of brackish water, insufficient and bad food, and physical and moral misery; 6th, to the want of proper drainage, and free ventilation in the streets, which is prevented by the huge projecting windows, and awnings spread across from house to house; 7th, to the evaporation from the salt marsh of Lake Mareotis; and lastly, to the mode of burial adopted by the modern Egyptians.

ON SOME POINTS CONNECTED WITH DIABETES.

By M. BOUCHARDAT.

Translated for the MEDICAL TIMES by ALFRED MARK- WICK, Esq., Surgeon to the Western German Dispensary, and formerly Lecturer to the General Hospital, Paris, &c.

(Continued from Vol. XV., p. 343.)

EXAMINATION OF THE MATTERS CONTAINED

IN THE DIGESTIVE APPARATUS, AND OF THE BLOOD AND URINE OF PATIENTS WHO HAVE DIED WHILE LABOURING UNDER DIABETES.

The prognosis of diabetes is always very unfavourable. The fatal terminations may be divided into two categories: in the first the patients die exhausted; in the second, death takes place suddenly, without there being anything in the general

condition of the patient to indicate the fatal issue.

When diabetes die slowly their end is always characterized by the development of tubercles in their lungs. This is a very remarkable circumstance, and one which I hope will throw some light on the etiology of tubercular disease. In these cases, that is, where death takes place slowly, no traces of sugar can be found, either in the matters contained in the digestive tube, the blood, or the urine collected from the bladder after death. I had noticed this fact before the publication of my last memoir, in which I thus explained it:—"These patients are on low diet for some days previous to the fatal result, as they take nothing but broth. It is easily understood, therefore, that the absence of glucose corresponds to the abstinence from feculents." This explanation may probably not be founded; and the fresh observations I am going to relate appear to prove so.

I said just now that patients affected with diabetes sometimes died suddenly. The cases in which I observed these sudden deaths to take place were only in persons who were strongly diabetic, and who eat a considerable quantity of feculents. Those who are submitted to a proper diet are not threatened with these sad results. One can easily imagine, and this fact is not peculiar to diabetes, that in patients whose constitution is undermined by a serious error in nutrition, and whose blood is modified, either by the presence of some foreign body, or by some permanent alteration, very slight accidents may prove fatal. These patients generally die suddenly, either from a serous effusion into the ventricles of the brain, or from pulmonary apoplexy. Owing to an obstruction of the perspiration, or to some other cause, a sanguineous congestion takes place towards the lungs, reaction is insufficient, and the patient dies asphyxiated in the space of a few hours. The two diabetes whose histories I am about to relate have died in this way.

Bert Emmanuel, aged seventeen, has entered and left the Hotel Dieu a great number of times. When he first came under our notice he had an ardent thirst and a considerable appetite, and voided from six to eight quarts of urine containing about 100 grammes of saccharine matter. After a month or two on a good regimen, his flesh and strength returned, the glucose disappeared from the urine, and he quitted the Hotel Dieu. But, from want of care, and the habitual and immoderate use of feculents, he returned very quickly to his former condition, and, of course, was glad to seek a readmission after he had exhausted the strength he had gained, and spent the trifle he had amassed in the hospital by selling to the other patients (notwithstanding the most attentive watching) a portion of the chosen food that was given him.

Fifteen days after his last exit from the Hotel Dieu he spent the remainder of his earnings in drinking and feasting, paying no regard to feculents. He became suddenly chilled, and was immediately afterwards seized with shivering, fever, and difficulty of breathing. He was brought to the Hotel Dieu, but he died five hours after his admission.

Post-mortem examination proved that he died from the effects of pulmonary apoplexy. His lungs, shrunken and gorged with black blood, had lost all their permeability. At the summit of the left lung a few crude tubercles were observed. The kidneys were of the natural shape, colour, and consistence, but were slightly increased in size; the other organs presented nothing abnormal.

I now come to the important question, viz.:—whether starch-sugar exists in the food contained in the stomach, or in the fluids, of diabetic patients who have died suddenly?

The stomach was large, and contained more than a kilogramme of a thick pappy matter, of a weak acid reaction, in which the remains of bread and other food were detected. This paste was diluted with twice its weight of water, and the filtered liquid examined with the polarizing apparatus, but there was no sign of any rotation observable; neither did the addition of yeast to the mixture occasion any alcoholic fermentation. The matters contained in the remainder of the intestines were likewise free from glucose.

I collected some blood from the heart and great vessels, and found, on a very careful analysis, that it yielded no trace of glucose. The bladder contained about 200 grammes of a light amber-coloured urine, of specific gravity 1.018, which, on being examined with the polarizing apparatus, in a tube of 303 millimetres, gave no indication of any rotation; and yeast occasioned no fermentation; in a word, it contained no glucose. I extracted from it, however, a very considerable proportion of urea and alkaline phosphate.

The next case I have to mention is, perhaps, still more remarkable. It is also that of a young man, less than twenty years of age, and of the most limited intelligence. The disease in all probability was of long standing, but it had only been lately detected. He lived in the country, where he was noted for his extreme voracity. Not only did he devour the ordinary pittance of the family, but he, moreover, lost no opportunity of begging or pilfering food; and he had even been frequently detected in the fields plucking up potatoes and eating them raw. He likewise stole beans, which he swallowed raw, and without condiments. His friends at last decided on sending him to Paris, where he became placed under the care of Professor Chenevix, who, before submitting him to any treatment, desired that the urine of twenty-four hours should be collected and analysed, and that his ordinary diet might not be changed.

He took in the twenty-four hours—

Bread	720 grammes.
Boiled beef	250 "
Potatoes	250 "
Wine	40 centilitres.
Broth	75 "
Common tissue . . .	litres.

He voided in the same space of time six litres and a quarter of urine, which contained 135.17 grammes of glucose per litre. This is the largest quantity I have ever met with.

The next day, at the visit, he slipped away and stole a loaf that was in the pantry, and immediately afterwards cat it, and also the remains of a poultice, in a cold damp place. After the visit he was seized with violent shivering, complained of pain in the side, and a difficulty of breathing, and eight hours afterwards he died suffocated.

Section cadaveris proved that death took place from the same cause as in the preceding case. The lungs, free from tubercles, were shrunken and gorged with black blood; the kidneys were hypertrophied, and their tissue rather paler than natural. The size of the stomach was enormous, and contained more than two quarts of a thick, pulpy, acid matter, in which the remains of bread were recognized. This pulpy matter was diluted with twice its weight of water, the liquid was then filtered and examined in a tube of 303 millimetres. It showed no sign of any rotation, and yeast occasioned no alcoholic fermentation.

The blood yielded no trace of glucose; the bladder contained about 120 grammes of a light-coloured urine, which was removed by means of a catheter; its density was 1.022 at 15°. Examined after being filtered in a tube of 303 millimetres, it was found to occasion no deviation, and yeast produced no disengagement of carbonic acid; neither did Frommherz's test show the presence of any glucose.

These are two very remarkable cases. They relate to two very strongly diabetic patients. The urine of one of them contained as much as 135.17 grammes of glucose per litre the eve before his death; and, although he was carried off by a disease of eight hours' duration, the urine present in the bladder at the time of death contained no trace of it; his stomach was full of food, the digestion of which had been suddenly interrupted, while the secretion of the diabetic diastase (and this ought to be carefully noted) was found to have been suppressed, together with that of the gastric juice, which serves to accomplish digestion.

Does it not appear to follow from these cases that the secretion of diabetic diastase, like that of the gastric juice, is intimately connected with the state of health? In fact, we know that the secretion of the gastric juice, possessing all the energy of its solvent properties, is in intimate relation with the healthy condition of the stomach and the re-

malander of the digestive apparatus. If the animal which is to supply the gastric juice is indisposed, instead of the normal liquid of digestion, we obtain aropy mucus, perfectly unfit for dissolving the food, or the solvent action of which is very considerably diminished. In persons labouring under diabetes, the secretion of diabetic diastase appears to me intimately connected with that of the gastric juice. It might be imagined from this, that this secretion is only the perversion of a physiological function.

ON THE NATURE OF DIABETES.

The thirst of patients affected with diabetes is in a direct ratio with the proportion of feculent food they take.

The quantity of water necessary for a diabetic, to enable him to digest *fecula*, is exactly equal to that which requires to be added to diastase to convert *fecula* into glucose.

The gastric juice of a dog, obtained according to M. Blondlot's process, does not dissolve bread or feculents any better than pure water.

The matters first vomited by a healthy individual, while fasting, have but a very weak solvent action on bread.

The matters vomited by diabetics, on the contrary, have a very powerful solvent action, and glucose may be easily detected in these solutions.

If the matters vomited by a healthy person, who two or three hours previously had taken a feculent repast, be collected, they will be found to contain but a very small amount of glucose; if, on the contrary, a diabetic is made to vomit two hours after a feculent repast, the presence of a considerable proportion of glucose may be very readily demonstrated in the vomited matters.

From these facts I conclude that diabetic patients digest feculents differently to healthy persons. I might also add, that, in health, man does not digest raw *fecula*; while, on the other hand, I have met with two diabetics in whom the grains of *fecula* were as easily attacked as in granivorous animals.

Why is it that the urine of diabetic patients who eat feculents contains glucose, while that of persons in health, who also eat feculents, does not?

This can only be ascertained by experiment. If an aqueous solution of half a gramme of glucose be injected into the veins of a dog, and the urine be removed from the bladder by a catheter two hours afterwards, it will be found to contain no trace of glucose. But if five grammes be injected, the urine will then contain a considerable portion. It may even be detected where two grammes are injected. If a dog is fed on soup containing one-tenth of glucose, traces of it may be found in his urine.

To the facts and experiments just mentioned, I may add the following:—

The solution of feculents takes place chiefly in the intestines, and particularly in the small intestines, but with very great slowness.

When animals are fed on feculent matters, the blood of the *vena portæ* contains a large quantity of both dextrine and glucose. These principles are also found in the bile.

From all these results we may draw the following legitimate conclusions:—

We find glucose in the urine of patients affected with diabetes, where they have ingested feculent matters, owing to these matters having been converted, under the influence of the diastase secreted in their stomachs, and the intervention of the water they have been compelled to take to allay an ardent thirst, into a solution of glucose; this solution becomes immediately absorbed by the numerous venous ramifications, the orifices of which terminate in the stomach, and is directly transmitted to the spleen by the *vana brevis*, and from thence poured into the torrent of the circulation. The necessary results of this rapid solution, this immediate absorption, and this direct entrance into the greater circulation, are, that the mass of blood contains a much larger proportion of glucose than five grammes; and that, as this principle cannot be destroyed in the blood, it is therefore eliminated by the kidneys. In consequence of the feculent food being so quickly dissolved and absorbed, the patients experience a sensation of emptiness and a desire to take fresh food, which,

if they are still chosen among feculents, serve only to employ the active powers of the digestive apparatus uselessly for nutrition.

In healthy periods the solution of cooked feculents commences in the stomach; but it is slow and limited, and an extremely small quantity of dextrine or glucose is absorbed at a time. The greater portion of the feculent food not dissolved passes into the small intestines, where its solution and absorption are more rapid; but nature has provided an admirable apparatus, so as to allow of only a slow and gradual introduction of these alimentary matters into the torrent of the circulation. It is not, as has been hitherto imagined, by the orifices of the lactals, that feculents converted into dextrine and glucose are absorbed: taken up in the intestines by the capillaries which empty themselves into the branches of the *vena portæ*, they thus become carried to the liver; a portion may be poured into the circulation of the hepatic vein, but the surplus is separated from the blood by the glandular apparatus of the liver, and secreted with the bile, with which it passes into the gall-bladder, and from thence into the intestines, to be again absorbed, and to follow the same course. Nature has thus restricted the consumption of these combustible materials, which should be but slowly mixed with the blood.

Thus, to resume in a few words the comparison between diabetics and persons in health, it may be said, that in the first the solution of feculents is rapid; and in the second, slow; in the first it takes place in the stomach, and the glucose which results is immediately, and in great part, carried into the blood; in the second it takes place chiefly in the intestines, and does not enter the greater circulation until after it has passed through the liver, and been usefully retarded by the small hepatic circulation. Moreover, if it be recollected that, when the quantity of glucose in the blood at one time is greater than two grammes, its presence may be detected in the urine, it will be readily understood why the urine of diabetic patients ought to contain saccharine matter, and why that of persons in health does not.

There are, perhaps, several other circumstances which render the destruction of the glucose in the blood of diabetics more difficult. One might imagine that a decrease of temperature, of one or two degrees at least, the existence of which, in the average, I have ascertained, in these patients, is not foreign to this effect. This decrease of temperature may be easily explained: 1st, by a larger proportion of cold fluids being ingested by these patients; and, 2ndly, by the useless expenditure of heat in effecting the conversion of feculents into glucose.

The treatment recommended by M. Bouchardat consists in forbidding feculent and saccharine food of every description; in preventing, if possible, all sudden chills, by warm clothing, particularly flannel, which has, moreover, the effect of restoring the functions of the skin, by keeping up a gentle moisture on its surface; (a); in taking gentle exercise where the strength of the patient will permit, and in having recourse to warm baths, sea-bathing, &c.

The diet may consist of all kinds of meat, cooked in any way, and rendered palatable by condiments; of salt and fresh water fish; of eggs and milk, or, what is better, cream; of cheese, and of vegetables of various descriptions: taken, however, in moderation, and with a plentiful supply of butter or oil, the flour in the sauces being replaced by the yolks of eggs and cream. The vegetables that may be permitted are spinach, endive, lettuce, sorrel, asparagus, French beans, Brussels sprouts, and greens, which latter may be usefully combined with salted pork and fat bacon, &c.

Watercresses, endive, dandelion, lettuce, corn salad, &c., may be eaten for salad; but they should be plentifully mixed with oil, and the addition of hard eggs is not unfrequently necessary.

A very tempting dish, and one well suited for

(a) ["The impermeable pills," the use of which I described in this journal for Dec. 5, will, I have no doubt, be found extremely useful for this purpose in these cases.]—TRANS.

diabetic patients, may be prepared with from gluten, perfectly freed from starch, grated Gruyère and Parmesan cheese, and butter.

For dessert the oleaginous fruits, such as olives, almonds, nuts, and walnuts, may be permitted; and occasionally, but only in very small quantities, apples, pears, cherries, currants, raspberries, strawberries, raisins, and pineapples.

All farinaceous food is to be replaced by gluten bread.

For drink, besides wine, already alluded to, broth will be found very useful. Coffee may be allowed, but it should be drunk without sugar, or, at least, a very small quantity only. Beer, and all sweet fluids, must be prohibited.

For quenching the thirst of diabetic patients M. Bouchardat gives the preference to the Seltzer spa or Vichy waters, either alone or in combination with an equal portion of wine. Weak wine and water is better than any kind of tisane. Infusion of hops, or of some other bitter, is sometimes beneficial.

All acid drinks are prejudicial: they saturate the free alkali of the blood, which prevents, as M. Chevreul has long since proved, the prompt destruction of the alimentary combustible matters incessantly introduced into the circulation through the medium of the digestive apparatus.

The therapeutic agents by which the hygienic means are best assisted are the carbonates of ammonia, already alluded to (a), and the preparations of opium, the preference being given by M. Bouchardat to the old electuary known by the names of mithridate and theriaca (theriague).

ON THE MEANS OF DETECTING THE PRESENCE OF STARCH SUGAR IN URINE, AND ASCERTAINING ITS QUANTITY.

[Among the various tests for sugar in urine that have been recommended, M. Bouchardat gives the preference to the milk of lime test; to Frommherz's test; and, for the precise determination of the quantity contained in a quart of urine, to M. Biot's apparatus.]

1. *Milk of Lime Test.*—It is well known that when starch sugar of commerce, or diabetic sugar (which is the same thing), is boiled with a solution of potash or soda, or with milk of lime, the mixture becomes brown, and assumes a darker colour in proportion as it contains a greater quantity of starch sugar (glucose); cane sugar does not produce this effect. I was one of the first to point out this difference, and this character which is so easy of detection. The presence of a decigramme of glucose in a quart of urine may thus be ascertained by an examination which is terminated in a few minutes and without any trouble; it being merely necessary to place in a matrass equal parts of milk of lime and the urine to be examined. Then, if the latter contain sugar, the mixture will turn brown, and, when we have a little experience in these examinations, we may judge, according to the darkness of the hue, of the approximate proportion of starch sugar contained in the urine examined.

I prefer milk of lime to a solution of potash, for two reasons—first, because practitioners in the country may procure lime anywhere: all they have then to do being to reduce about 50 grammes of quick limestone to powder by means of a little water, and afterwards to well mix it with about a quart of that liquid; it must be well corked and shook before it is poured into the matrass; and secondly, because several of the extractive matters of the urine are coloured by potash, which is not the case with milk of lime.

Nearly all my diabetic patients who live in the country examine their urine every day by this process; they can thus follow the progress of their treatment, particularly when they take care to measure the quantity of urine they pass in the twenty-four hours.

I cannot too strongly recommend this very simple method of examining the urinary secretion.

2. *Frommherz's Test.*—This is an extremely sensitive one, and is thus prepared. Equal parts of

sulphate of copper, and tartrate of potash, are separately dissolved in water; the two solutions then mixed, and caustic potash added in sufficient quantity to dissolve in a great measure the precipitate. A liquor of a beautiful blue colour is the result. In examining the urine, a sufficient quantity of this test should be added to it to give it a slightly alkaline reaction, and the mixture then boiled, when, if the urine contain no starch sugar, the liquor remains blue; but if it does, the salt of copper becomes reduced, the liquor changed to a reddish-yellow colour, and a deposit of red oxide of copper soon formed. It sometimes happens that urine which contains no glucose becomes changed in colour by boiling; this is owing to the presence of other organic matters in the urine, and which have also a reducing power. Therefore, I have not confined myself to Frommherz's test, although I have frequently had recourse to it; but it is only in doubtful cases that there can be any difficulty; where there is a considerable quantity of glucose in the urine, the reduction of the salt of copper and the deposit of the oxide are to such an extent as to leave no doubt on the matter.

3. *M. Biot's Polarizing Apparatus.*—Formula for finding the absolute weight of pure diabetic sugar contained in a quart of suspected urine.—It appears from the experiments of M. Biot, on pure diabetic sugar, that if diabetic urine be examined in a tube, the total length of which in millimètres is L, and that the deviation measured with the naked eye for the extraordinary violet-blue tint, which immediately precedes the yellowish-red, is α , the absolute weight of sugar contained in a quart of this urine will be, in grammes,

$$2353 \cdot 6 \cdot a$$

L

If the length of the tube is less than 350 millimètres, and the blue and yellow colours are very apparent, in consequence of the slight coloration of the liquid, this estimate will be too large rather than too small; if, on the contrary, L is greater than 350 millimètres, or the urine is sufficiently dark coloured for the colours to differ but little from one another, both before and after the point of passage, the estimate will be too small rather than too large. In any case the uncertainty will be of little consequence, particularly for the diagnosis. It depends on the difference occasioned by the more or less deep colour in determining the point of passage, where the deviation is measured when observed with the naked eye; this, however, may be obviated by always examining it through a red glass, which renders the deviations exactly similar; but, in this case, this made the examinations much more difficult, and without any actual advantage.

The two following examples show the applications of this formula:—

1. Diabetic urine was examined in a tube, of which the total length L was 500 millimètres, and a deviation α , equal to 13° , was observed. By multiplying 2353.6 by 15 we obtain 35304, which being divided by 500 leaves 70.608 gr., which is the weight of sugar contained in each quart of urine examined; this estimate, however, is too small rather than too large.

2. The tube was 347 millimètres in length, the deviation α $10^\circ.967$, and the urine very dark coloured through this thickness. By multiplying 2353.6 by 10.967 we obtain 24870.5, by neglecting after the multiplication the decimals, beyond the tens; then, by dividing this by 347, the quotient will be 71.673, which is the weight of diabetic sugar contained in each quart of the urine; although this estimate is, perhaps, less than the actual amount, owing to the urine appearing very dark coloured in the tube. (s)

10, Langham-place.

(To be continued.)

Erratum.—At page 342, column 1, line 19, for "are effects," read "an effect."

(a) According to my calculation the product would be 25811.0, and the quotient 74.385.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF SCIENCES.

Meeting of Feb. 22; M. BRONGNIART in the Chair.
INHALATION OF ETHER.

M. Flourens read a short account of some experiments made on the spinal chord of animals, placed under the influence of ethereal ebriety. Muriatic ether had yielded in the author's hands as decisive and more prompt effects than sulphuric ether.

Several communications of secondary interest were made on the same subject, by Messrs. Amussat, Laugier, and Gerdy.

A NEW METHOD OF DISTINGUISHING REAL FROM APPARENT DEATH, BY DR. MANDEL.—The author asserts that cauterization will invariably permit the distinction: on dead tissues, a blister is never raised by the application of heat; but this effect is always produced on the skin so long as life persists. It remains to be proved how far the assertion is correct—in those cases where vitality is so latent and obscure that death may be supposed to have occurred.

ACADEMY OF MEDICINE.

Meeting of Feb. 23; M. BEGIN in the Chair.
ETHEREAL INHALATION.

A letter was read from Dr. H. Wells, Connecticut, U.S.A., claiming the merit of the first application of the system to surgical operations. The protoxide of azote Mr. Wells now prefers to ether.

M. Orfila stated that Vauquelin and himself had unsuccessfully endeavoured to inspire the nitrous oxide gas; Davy had asserted that it produced considerable exhilaration; M. Orfila experienced nothing of the kind.

M. Gérardin said that fifteen or eighteen years since, a letter had been received from an English physician, who asserted that, by inhalation of laughing-gas, he could render patients insensible to pain during surgical operations. This letter caused a certain sensation in the academy; some members treated it with contempt, but Baron Larrey defended it, and offered to try the experiment. M. Gérardin would look in the archives of the academy for the letter.

Professor Dubois remarked, that although the subject had already occupied on several occasions the attention of the academy, still the special application of the new method to the purposes of midwifery would doubtless give his present communication a certain share of interest and importance. M. Bouvin and Professor Velpeau had both expressed the opinion that the obstetric art would find in ethereal inhalations a useful assistant: it is probable that these two gentlemen had only inferred the supposition from what they had repeatedly observed of the effects of ether in surgical operations. M. Velpeau had also hinted that the inhalation might possess the power of preventing certain muscular actions, from which arises the chief difficulty in the execution of some obstinate operations—that of turning the child, for instance. It had been elsewhere supposed that the new method would prevent the pain which would attend the natural labour; and this hope was, in some measure, realized. The object of the present communication was twofold: in the first place, to discover if the inhalation of ether could render obstetrical operations painless; and in the second, to ascertain its effects upon the pains of natural labour? Both these questions were intimately connected with others which the author thought it necessary to examine.

When the learned professor began his researches, he had experienced a considerable degree of embarrassment, not unmixed with scruple, from the absence of any guide, on precedent, from which he might gather some degree of security in the application of the new method to parturient women. The first questions to be ascertained were the following:—Would inhalation of ether be injurious to

the mother? would it be prejudicial to the child? would it exert its noxious influence in a primary manner? or, by its stupefying action on the spinal chord, might it not paralyse the contractions of the muscular structures of the womb? Further—supposing it demonstrated that its primary action was injurious to neither of the two beings concerned—might it not prove consecutively hurtful to their constitution?

With regard to the child, the penetration of ether into its system was in itself a circumstance which might doubtless explain a certain amount of anxiety, and facts have proved this anxiety to have been founded upon proper grounds.

As to the safety of the mother, the question contained more special elements. The ethereal obriety was at its beginning characterized by convulsive movements, and often tetanic agitation of the voluntary muscles. The intoxication was also sometimes followed by a semi-epileptic condition: now, the frequent occurrence of convulsions during the puerperal state, and their too frequently fatal termination, were circumstances which naturally obliged Professor Dubois to pause before exhibiting ether during parturition. This hesitation was further justified by the recollection of the cases of hysteria, related by Professor Piorry, in which that gentleman observed that the inhalation of ether aggravated the symptoms, instead of amending them. Professor Dubois thought he was not mistaken when he said that a physician had exhibited the ether in cases of epilepsy, and was obliged to abandon the system on account of the increased severity of the fits: in an English medical paper, a case of tetanus was related, which had been unsuccessfully treated by ethereal vapour. In his own cases, Professor Dubois had been so fortunate as not to have any confirmation of his fears on this point.

In order to prove that ethereal inhalations prevent pain during obstetrical operations, the learned professor related two cases, of which the following is a brief abstract:—

CASE 1.—A young woman, aged eighteen, primipara, entered the Hospital of La Maternité on the 6th of January, after thirty-eight hours' labour. Perforation of the membranes, and the ergot of rye, not having produced any acceleration, the application of the forceps was resolved upon, ethereal insensibility having previously been induced by six minutes' inhalation. Some movements being observed, which gave doubts as to the state of insensibility of the patient, the inhalation was resumed during five minutes, when the instrument was introduced, the head extracted, and delivery completed without any pain; expansion of the vulva and perineal dilatation were accomplished more rapidly than usual. The child was alive; the chord presented at first 160 pulsations per minute, and they fell, in the space of ten minutes, to their natural standard, viz., 136.

CASE 2.—A woman, aged nineteen, at the last period of utero-gestation, had been thirty-six hours in labour. The inhalation was continued for ten minutes, when insensibility was in appearance induced; but, to ensure unconsciousness, the ether was again exhibited during five minutes, when the patient fell into a state of stertorous sleep. The forceps was introduced, and the delivery completed without pain; the woman, however, appeared conscious of the operation.

Professor Dubois stated that analogous results had been obtained by others, namely, Dr. Fournier Deschamps, in a case of application of forceps; Dr. Simpson, of Edinburgh, in a case of turning; and Mr. Skey, of Bartholomew's Hospital, London, in a patient who bore without pains the Cesarean section.

Professor Dubois next examined the influence of the ethereal inhalations on uterine contraction, and on synergetic action of the abdominal walls. At the present period the question of the origin of the uterine nerves was still pendent: from the fact, however, that the womb cannot regulate or in any way modify its own contractions, M. Dubois was of opinion that its nerves were, if not exclusively, at least almost all,

derived from the sympathetic system; and if any nervous twigs were sent to the uterus from the cerebro-spinal axis, their connection with the latter was most probably indirect: hence the professor would feel inclined to conclude, *a priori* that ether, acting exclusively upon the organs of animal life, ought not to suspend contractions placed in the immediate dependence of organic vitality. M. Brachet, of Lyons, held a contrary opinion: from experiments on animals, and divisions of the spinal cord in various regions, he concluded that the contractions of the uterus were under the influence of the nervous centre; he also derived his conviction on this subject from a case of paraplegia, which he observed during pregnancy. The physiological experiments of M. Brachet, Professor Dubois was not prepared to call into question; but the case of parturition in a paralytic woman did not present the signification allotted to it by M. Brachet, for in this instance the forceps was applied after complete and spontaneous dilatation of the os uteri—a circumstance which necessarily implied contraction of the walls of that viscus. The following cases would tend to throw some further light upon these obscure points.

CASE 3.—On the 5th of February, at the Hospital of La Maternité, M. Dubois applied the method of inhalation in the case of a woman who had been already eight hours in labour-pains. The dilatation of the os uteri was equal to a crown-piece, and the uterine contractions were powerful and frequent; the membranes, however, had not yet yielded. After twenty-five minutes' inhalation, unconsciousness was established (the ethereal inspiration had been frequently interrupted). At that moment congestion of blood suddenly took place towards the head, the face becoming flushed, the conjunctiva injected to that degree that M. Dubois imagined that blood might spring from its surface; the tongue was turgid, the lower lip pendent, and a spumous saliva was expelled from the mouth. During this state, which lasted three minutes, the uterine contractions distinctly continued, and without pain. The fetal heart was auscultated, and 160 pulsations were counted in a minute. The woman soon after recovered consciousness, when the fetal heart came down to 136; and she declared she had experienced no pain whatever.

CASE 4.—A woman, arrived at the termination of her second pregnancy, was in pains for several hours, when Professor Dubois was called to her. The pains were extremely violent, and the screams of the patient loud and incessant. After inhaling ether during three minutes, she became insensible, and the uterine contractions continuing with energy, and the membranes protruding vigorously against the finger introduced into the vagina, from the time unconsciousness was established, the perfect quietude of the patient contrasted powerfully with the energetic action which was rapidly proceeding in the womb, and formed one of the most striking and unusual phenomena ever observed in the practice of midwifery. The membranes were ruptured, and delivery speedily followed. On recovering consciousness, the patient declared she had not suffered, but had dreamed. The nature of her dream she at first refused to explain, but afterwards related to one of the nurses that she fancied herself lying by the side of her husband, and that they had been simultaneously engaged in those preliminaries, the result of which had been the condition in which she then was.

With regard to the effects of the inhalation upon the contraction of the abdominal muscles, Dr. Dubois related a fifth case, in which their contraction had been specially examined, and had been perfectly complete and satisfactory, notwithstanding the complete insensibility of the subject. In all these cases Professor Dubois had been struck with the facility with which perineal distention was accomplished; in none did the patients experience any bad results from the inhalation of ether. The two cases in which the application of the forceps was necessary terminated fatally from puerperal peritonitis; but, at

the same time, several other cases of puerperal peritonitis were extant in the wards; some of the latter died, and the anatomical appearances after death were exactly and precisely the same as in the two cases in which ether had been employed. The inhalation cannot, therefore, be looked upon as having been the cause of death in these two cases; besides, in one, labour had lasted forty hours, in the other, thirty-nine, before the application of the instruments. The conclusions which Professor Dubois adopted, and which he laid before the academy, were the following:—Ethereal inhalations can prevent pain in obstetrical operations; and they suspend provisionally the natural pains of labour, without interfering with the uterine or abdominal contractions. Their influence tends to weaken the natural resistance of the perineum to dilatation, and does not seem to be injurious to the child.

With regard to the practical application of the method to obstetrics, M. Dubois thought it would seldom be used, on account of the difficulty of procuring a fit apparatus in sudden emergencies; and that the greater facility which Professor Velpeau supposed the inhalations would give, for turning the child, did not in reality exist, as the uterine contractions were proved to continue during insensibility, with undiminished energy.

After a short debate, in which Professor Velpeau and M. Malgaigne expressed their surprise, that after proving that ethereal inhalations were innoxious to child and mother, prevented pain, and facilitated perineal distention, without interfering with uterine or abdominal contraction, Professor Dubois had shown so much reserve in speaking of their practical application to the art of obstetrics.—The meeting adjourned at half-past five.

PARISIAN MEDICAL SOCIETY.

Meeting of Feb. 24; Dr. SHERRINGTON in the Chair.

ETHEREAL INHALATION.—PRIORITY OF INVENTION.

Dr. Wells, a visitor, requested and obtained permission to make the following communication:—

It was in November, 1844, that this idea of forming painless operations had first occurred to Dr. Wells; and the observations arose from the frequent absence of pain in wounds inflicted upon persons labouring under strong excitement. In November, 1844, Dr. Wells had already inhaled nitrous oxide gas, and ether, but he vapours of ether he did not bear so well as those of the nitrous oxide; and at that time Dr. Wells had a tooth extracted during the insensibility induced by the inhalations; twelve or fifteen operations of the same kind, and quite free from pain, had been performed by him at that remote period. Shortly afterwards, Dr. Wells came to the city of Boston, and communicated the discovery to Dr. Warren, who permitted him to deliver on the subject a lecture to his (Dr. Warren's) class. One operation was then performed, and the insensibility of the subject not having been perfect, pain was experienced, and Dr. Wells denounced as an impostor. The discovery had been communicated to Dr. Mott and Dr. Jackson. Mr. Morton, a pupil of Dr. Wells, had also been initiated. Under these circumstances Dr. Wells came to Europe, and to his utter amazement, when unprovided with the printed proofs of the facts he stated, the discovery was published and claimed by Dr. Jackson and Mr. Morton. One American periodical, of Dec. 16, 1845, Dr. Wells had found in Paris, and that paper contained a letter from a Mr. Ellsworth, in which the discovery was claimed in favour of Dr. Wells, and reference made to an article published on the subject in the same paper twelve months previously.

FACULTY OF MEDICINE.

LECTURES ON GENERAL PATHOLOGY, BY PROFESSOR ANDRAL.

Plasticity is another vital property, exclusively belonging to organized beings; it includes the

phenomena of assimilation, and of healthy or pathological nutrition.

That power by which is produced animal heat, and the resistance which living matter opposes to the establishment of equality of temperature in all bodies placed in the vicinity of each other, is also a vital property, towards which we must direct your attention. The physical and chemical phenomena, which succeed each other uninterruptedly in our system, are doubtless the agents of the production of heat; but life is the indispensable condition of the maintenance of that heat at its average standard. Man has a temperature proper to himself; he can rid himself of a superabundant amount of heat, or regain the losses of caloric caused by the vicinity of cold substances; this power has certain limits, beyond which it ceases to exist. The increase of heat is the principal characteristic of one great morbid entity, viz.—fever; its diminution is also observed in disease. It may be laid down as a general principle, that the temperature of all beings is in proportion with the quantity of oxygen which they absorb from the atmosphere. Thus mammalia and birds, particularly the latter, consume a large quantity of oxygen, and are endowed with very energetic calorificity. The average temperature of the human body, in health, oscillates between $+36^{\circ}$, and $+38^{\circ}$ Cent. (96° — 100° F.). Man can continue to live, and even permanently, in a medium far inferior in temperature to the heat of his own body; life can still be preserved at the freezing point of mercury. Heat is not so well supported, for life cannot continue when the body is placed in an atmosphere heated to $+55^{\circ}$ Cent. (131° F.); that heat can be borne only in a transitory manner.

The human body does not rise in temperature when placed in a medium somewhat above its own; perspiration breaks out, and the heat is subdued. If, however, from any reason, perspiration does not occur, the heat of the body rises slowly; it has been known to gain 2, 3, 4, and even 5 degrees C. (3.6° — 5.6° — 7.2° — 9° F.); but an augmentation of four and five degrees has only been observed when the temperature of surrounding bodies had been raised to 70° to 90° C. (158° to 194° F.). Dr. Robert Latour, in some researches on the hydropathic treatment, asserts that, in the packing process, the heat of the body never rises more than 3° above its natural standard.

Mr. John Davy, in some interesting remarks on this subject, observes that the average degree of heat proper to the human body seems to increase gradually from the poles to the equator. Captain Parry noted the temperature of the body of the men under his command, in the polar regions, and found that, although the thermometer had fallen somewhat below the freezing point of mercury, the temperature of the body in the axilla, and at the orifices of mucous membranes, was not evidently modified. It must be added that the men were extremely well fed, and in excellent spirits.

When, however, the cold is more intense, the heat of the body gradually yields—in the surface at first, and afterwards in the more central parts.

Temperature in man varies slightly with the constitution peculiar to each individual: thus, after cold ablutions, reaction is, in some persons, so very slow as to render them in some degree perilous. On this point an interesting publication of Dr. Currie may be consulted with advantage. The production of heat is less perfect immediately after birth, and its insufficiency is in proportion to the backward state of development of the being observed. In this respect, Mr. Edwards divides animals into two classes: those who are born with, and those who are born without, a pupillary membrane; in the former, calorificity is not by any means so energetic as in the latter. The same observation applies to the human species: when the child is fully developed, its average heat is 34° or 35° ; when the accouchement has been premature, the body of the infant presents only 33° or 34° . Dr. Roget, in a valuable paper relating to this question, states that on the instant of expulsion from the womb

the axilla of the child presents a heat of 37° (98.6°), and falls after some minutes to 35° (95°); thus proving that a portion of the heat of the infant's body is derived from the medium which he has so recently abandoned. In the space of twenty-four or thirty hours after birth, the temperature of the infant increases, and equals that of the adult— 37° , although the maximum of the physiological heat of the latter, 38° , is never observed in the newborn. No rigorous observations have hitherto been made for the purpose of ascertaining the temperature proper to the aged. In disease, old persons appear to cool faster than younger individuals, but thermometric investigations are wanting to demonstrate the fact. The aged consume less carbon—a remark which certainly implies the production of less heat.

The state of the nervous system, the composition of the blood, doubtless exercise some influence upon the production of animal heat. With regard to nervous influence, no definitive result has yet been obtained. Numerous experiments have been instituted, wherefrom the induction has been made, that diminution of nervous influence causes a decrease of temperature; but the problem appears to us to present so many elements which have not been taken into account, that the inference does not appear to be perfectly justifiable; thus the destruction of motion in muscular textures would in itself account for diminution of temperature. The influence of narcotics on calorificity has not been studied. With regard to mental emotions, it is true they often produce a sensation of intense cold in the skin; but thermometric research is absent, and, until demonstration has been obtained, we must consider the chill and cold which attend emotions as the result of a new and vicious repartition of animal heat. Slep has been said to cause a diminution in the temperature of the body; but it is accompanied with repose from muscular exertion—a circumstance sufficient in itself to explain loss of heat. Becquerel and Breschet have shown that a thermometer placed in a muscle in a state of contraction rises half a degree; consequently paralysis will cause diminution of the heat of the diseased part.

The arterial is usually warmer by one degree Cent. (1.8 Fahrenheit) than the venous blood: diminution of the globules, or of the fibrine naturally contained in the circulating fluid, makes no change in its temperature. As to the rapidity of the circulation, it certainly does in general coincide with increased heat of the body; but these two phenomena do not seem to be in absolute dependency of each other; the pulse may be very frequent, and the skin not very hot, and, reciprocally, the skin be hot and the pulse slow; but suspension of the circulation may be said to coincide always with a diminution of the heat of the body: thus, when an artery has been tied, the temperature of the part which it is distributed to, falls, but only after fifteen or twenty minutes—a fact which Becquerel and Breschet have satisfactorily demonstrated. When blood is accumulated in any organ without disease, the heat of that organ may be slightly increased, but it never rises higher than the temperature of the axillary region.

It is of great importance in disease to distinguish the real diminution of the temperature of the body from an apparent decrease due to unequal repartition of animal heat. In the latter case the temperature of the axilla remains always at its healthy standard. This is observed in violent pain, in colica nephritica, in peritonitis; and remark, also, that in the cold which is observed when corrosive poisons are introduced into the stomach, or in syncope, or, again, in certain affections of the heart, which interfere much with respiration, the temperature of the axilla remains at its healthy standard, although the heat of the remainder of the body has notably decreased. The same remarks apply to cholera, a disease remarkable by the refrigeration of the surfaces, and the oedematous swellings of the body.

Having thus clearly established the meaning

of those words—"unequal repartitions of heat"—let us examine the local or general modifications of animal heat in disease.

We have said that in health the temperature of the human body oscillates between 36° and 38° — 37° being its average amount. The maximum of heat which the body has ever attained under morbid influences is 42° , and in the infant 42.5 (Roget); but this increase is very exceptional, and from 38° , the maximum during health, we may say that in general the increase of heat brought on by disease varies from 1° to 3° Cent. This increase of temperature constitutes fever; whether it be idiopathic or symptomatic—produced by an acute affection like pneumonia, or accompanying a chronic alteration like tubercle; whether inflammatory or adynamic, continuous or intermittent—fever is always attended with increased heat of the body: in ague we find it during the three periods of fever, and the chemical condition of the blood does not influence this indispensable element of febrile excitement, the intensity of which will be always in proportion with the degree of heat. At a period when the exploration of the pulse was not in use, Galen recommends the application of the hand on the thoracic walls, in the vicinity of the axilla, in order to judge of the existence of fever, from the presence of unusual heat. The very word *perplexia* ($\pi\alpha\upsilon\varsigma$) implies the admission in former days of the opinion which we have just laid before you.

We must very clearly establish the fact that all the causes which have the power of producing fever act in producing in the organs a modification by which heat is evolved. This modification, these new conditions, are most probably connected intimately with the phenomena of nutrition, and with a more abundant combustion of hydrogen and carbon. It would be a curious and valuable experiment to ascertain it during fever—more carbonic acid is evolved from the body than during pyrexia: indeed it is highly probable that such is the case. Let us, however, say that plausible such a theory may appear, powerful objections can be raised against it; thus, many accelerations of circulation, brought on by weakness, abundant hemorrhage, insufficiency of aortic valves, &c., are not attended with increased heat: in the newborn infant the pulse is quick, the respiration frequent, and still the temperature of the body is not above the average amount observed during health. Let us now examine the influence of various diseases upon the elevation of heat. In 366 cases of numerous maladies, all attended with fever, we found at the axilla—

In	64 cases	38° Cent.	100° F.
156	"	39	102.2
116	"	40	104.0
18	"	41	105.8
1	"	41.8	107.24
1	"	42	107.0

In ninety cases of typhoid fever the following results were obtained:—

In	12 cases	38°
26	"	39
43	"	40
8	"	41
1	"	41.8

In this malady we have often observed the pulse slow—at 70 , for instance, whilst the temperature of the axillary region remained above the average of health: this is peculiar to the adynamic form. On the contrary, we have noticed cases in which the pulse remained frequent, although the thermometer in the axilla did not show any increase of heat; in these instances the fever had left, and the quickness of the pulse was evidently due only to weakness—a practical distinction, towards which we cannot sufficiently call your attention.

In fifteen cases of variola the temperature varied from 38° to 40° .

In eleven cases of measles it oscillated between 37.5 and 40° .

Scarlatina is attended with great development of heat; we have examined seven patients with the intention of ascertaining the fact: in two we

found, 39°; in five, the thermometer rose to 40° and 40°·5.

One case of acute fever came under our observation: the heat of the body was equal to 42°.

The elevation of temperature during the paroxysms of ague, and particularly during the rigor, had been formerly noticed by Martin (quoted by Haller), and lately by Professor Gavarret. Whilst the extremities are cold, the axilla, on the contrary, presents a heat of 40°·5, which continues to rise during the stage of calor, and it has been observed to attain 41°. During a pyrexia the heat is natural.

Turning to investigations of the same nature in febrile excitement resulting from phlegmasia, we find seventy-three cases of pneumonia thus divided:—

11	2 cases	38°
28	"	39
10	"	40
11	"	41

In capillary bronchitis, in acute pharyngitis, in peritonitis, we also observed an oscillation of the thermometer from 38° to 40°.

Erysipelas and articular rheumatism were accompanied with the same increase of heat; in thirty-eight cases of rheumatism we found:—

38°	9 times
39	20 "
40	9 "

In the hectic fever of chronic disease we have always observed elevation of temperature: twenty-one cases of the sort were submitted to thermometric observation, and were examined in the morning; we found:—

11	14 cases	38°
10	"	39

The same results we had also obtained in carcinoma uteri, and other organic affections, their last period.

D. McVINEY, D.M.P.

Great Britain and Ireland.

LAW OF THE METAMORPHOSIS OF THE TEXTURES OF THE HUMAN BODY.—Physiologists are agreed that this metamorphosis in the human structure occurs in the following order:—viz., "from soft, semi-fluid, incoherent corpuscular textures, to the coherent cellular, from these to fibrous, fibro-cellular, and cartilaginous; and, lastly, to bone." This is observable from the earliest embryo to the adult. The analogous fact is recognised in vegetable structures:—viz., "cells containing a viscous, colourless mass, mixed with granules everywhere," as Mohl observes, "preceding the first solid formations." Dr. Addison gives the following remarks on the structure of the lungs:—

"The air-cells of the lungs are not indiscriminately thrown together in the interior of the organ; on the contrary, they are symmetrical with the branches of the air-tube, and collected or associated in numerous small communities or groups, each group forming what is termed a lobule; many lobules grouped together form a lobe, and five lobes form the two organs called the lungs. A pulmonary lobule is a perfect respiratory organ in itself, the whole lung being but a series of reduplications of the same structure—an aggregate of lobules. At one of the corners or angles of a lobule a division of the air-tube and an arterial blood-vessel enter into its interior, and at the same place a vein comes out, and by these three cylindrical structures the lobule is connected with its fellows. The membrane which forms the walls of the air-cells constitutes the *parenchyma* or proper texture of the lungs, and the capillary vessels so densely distributed upon it have no other coats or boundaries than those furnished by this parenchymatous texture. The practical point to be insisted on, with a view to the correct understanding of the pathology and diseases of the lungs is that involving the relation of the walls of the air-cells to the extremities of the air-tube on the one hand, and to the blood-vessels on the other.

"The air-tubes and blood-vessels, before entering

into the interior of the lobules, run into the spaces between them, and here, cushioned, as it were, upon an areolar texture, they have severally their own distinctive elements and structures; but within the lobules, after sundry subdivisions, they all terminate in, and their textures become continuous with, the walls of the air-cells—that is to say, with the parenchymatous texture; and here it is impossible, even with the microscope, to discriminate between the elements continuous with, or prolonged from, the coats of the blood-vessels, and those continuous with, or prolonged from, the air-tubes—that is to say, in other words, the outer surface of this transparent wall of every air-cell is in close relation with the interior of the blood-vessels, and its inner surface is as closely related to the air-tubes.

"The parenchyma of the lung is usually described by anatomical writers as a mucous texture—that is, a secreting texture; but it has none of the anatomical characters of a mucous texture; its perfect transparency and elasticity resemble much more the characters of a fibrous or serous texture; moreover, it is well known that its capillaries have a special function, and no analogy whatever exists between them and the capillaries of a secreting texture. In the adult lung the parenchyma is *coherent-cellular*, the areolar texture interposed between the lobules is *fibrous* and *fibro-cellular*, the plasma which covers the whole lung, and lines the interior of the cavity of the chest, is both *cellular* and *fibrous*—cellular on its smooth free surface, and fibrous beneath. The mucous texture of the interior of the air-tube is *fibro-cartilaginous*—that is, composed of fibres intermingled with incoherent cells; and the blood is a *corpuscular fluid*, flowing in streams over the walls of the coherent cellular parenchyma. But in the embryo all pulmonary textures are composed of soft and but slightly cohering cells: in the foetus they are partly corpuscular, and partly coherent-cellular; and during infancy and youth the walls of all the nutrient vessels, even of those which have become fibrous, are largely charged with incoherent corpuscles or cells. Hence, then, the morphology of the textures of the lung is *corpuscular*, *cellular*, and *fibrous*; and there is nothing, except in the larger branches of the air-tube, of a cartilaginous or osseous texture.

"**PHYSIOLOGICAL ANALYSIS OF THE CORPUSCULAR, CELLULAR, AND FIBROUS TEXTURES.**

"Aspiring in view the distinctions insisted on between the *corpuscular* and the *cellular* textures, it is evident that the corpuscular are the secreting textures, and the cellular the non-secreting ones,—that is to say, the cells or corpuscles of the secreting textures, with their thin walls and elaborated contents, are temporary and evanescent elements; while the cells of the coherent-cellular textures, with their strong elastic and transparent walls, are comparatively durable and permanent; and as the rapidity of the changes and displacements which the elements of a structure undergo is in a direct ratio with their importance in the functions of nutrition, secretion, and life, so therefore the cells or corpuscles of the corpuscular textures are more active or energetic than the cells of the cellular.

"Again, contrasting the corpuscular with the fibrous textures, the latter perform the comparatively mechanical offices of separating, investing, and limiting in bulk, the different groups of the various corpuscular and cellular textures, engaged in the more active functions of life, transmitting the larger columns of blood to and from them. These functional distinctions are indicated by the anatomical fibrous element, and by the species of polarity observable in the texture. The corpuscular or secreting textures are everywhere traversed by multitudes of nutrient vessels, specially disposed in different organs; whereas the fibrous non-secreting ones, although in some instances extremely vascular, in consequence of having to transmit multitude of small vessels, have yet comparatively few nutrient capillaries, and these variable and irregular in their disposition. The dura mater and pia mater are both fibrous membranes, surrounding, supporting, and protecting, in bulk, the whole brain or central organ of the nervous system. The dura mater, as its name I suppose implies, is an exceed-

ingly strong and coherent texture, transmitting immense columns or streams of blood to and from the brain, yet is itself scantily supplied with nutrient capillaries. But the arterial currents traversing the dura mater, and those still larger ones arising from other quarters, before they can be admitted into the soft corpuscular texture of the brain, must be divided and subdivided many times into the smallest possible streams, and the force of the heart's action subdued by sinuous turns and windings. For these ministerial purposes the much more fine and delicate fibrous texture of the pia mater is interposed, which not only affords space and area for the subdivisions of the blood-current, thereby becoming extremely vascular, but, slipping down between all the lobular subdivisions of the organ (here termed convolutions), it enters into the recesses, supporting and limiting and conveying vessels, through which the blood reaches and returns from all parts of the soft and tender parenchyma of the great organ of life and being. Lastly, the cellular parenchyma of the lung is not tender, opaque, and brittle, like the corpuscular parenchyma of the liver, but is, on the contrary, exceedingly coherent, elastic, and transparent; and these anatomical characters indicating, as before observed, that the parenchyma of the lung is not a place of active nutrition or cell-elaboration,—not a secreting texture; and although eminently vascular, more so, perhaps, than any other texture of the body, still the vascularity is analogous to that of the pia mater—a ministerial and not a nutritive vascularity, the analogies of the texture being altogether with the fibrous non-secreting, and not with the corpuscular and secreting textures. This corresponds with facts; the only outlet and inlet to the lungs is by the windpipe; and if the air-cells, which have been computed to number 1,744,000,000 in each lung, or if an expanse of membrane equal in area to 1,500 square feet, were a secreting membrane in the ordinary and proper acceptation of the term, persons would be always swallowing, or spitting, or coughing, which we know in health is not the case. The fine transparent cellular texture of the pulmonary parenchyma allows the finer and vaporous elements of the blood to transude its wall, but it does not, I conceive, in the proper sense of the word, give rise to a secretion."

The Part where Fecundation takes place in the Human Species and in the Mammalia.—M. Coste has demonstrated that at the period of sexual desire, the graafian vesicles become constantly the seat of tumefaction—the precursor of their approaching rupture and the spontaneous escape of the ovum. By experiments practised on fecundated rabbits, M. Coste has demonstrated the presence of ova in the superior half of the ovarian tube, covered with spermatozooids. This, therefore, from numerous observations, is the situation where fecundation usually takes place; and further, he believes that fecundation occurs in the uterus, or in the uterine extremity of the tubes, only when the female having been kept apart from the male, receives the embraces of the latter, after the rupture of the graafian vesicles and the escape of the ovum. To recapitulate, fecundation takes place sometimes in the ovary, usually in the superior half of the tubes, rarely at their inferior extremity, and still less frequently in the uterus itself.

New Remedy against Strangury.—The poison which serves as a defence to the bee is supposed to be the agent in relieving strangury in the following recipe. From 50 to 60 bees are thrown into a vessel of water. They are then transferred to a cup of tea, and boiling water is poured over them; cover the cup and strain the infusion, which is to be administered in one draught. The strangury ceases in a short time, varying from two to fifteen minutes.

OBITUARY.—At Carlisle, in the Crescent, on Saturday, Ralston Atkinson, Esq., M.D.—On the 6th instant, sincerely regretted by his numerous friends, aged 42, Mr. Fell, surgeon, Paddington.—On the 5th instant, at Paris, in his 74th year, Baron Pasquier, first surgeon of the King, inspecting surgeon and member of the Board of Health of the Army, and commander of the Legion of Honour.

REVIEWS.

A Manual on the Principles and Practice of Ophthalmic Medicine and Surgery. By T. WHARTON JONES, F.R.S.; Lecturer on Anatomy, Physiology, and Pathology at the Charing-cross Hospital; Foreign Member of the Royal Medical Society of Copenhagen; Corresponding Member of the Imperial Royal Medical Society of Vienna, &c. &c. London: John Churchill.

The following remark has been made by a physician: "We find in the eye more satisfactory and plain illustrations of the general facts and doctrines of pathology, than in any other single organ of the body." And further, he quotes from Dr. Latham's excellent work "On Clinical Medicine"—"From the peculiar structure of the eye, you see the morbid phenomena as through a glass, and you learn many of the little wonderful details in the nature of morbid processes which, but for the observation of them in the eye, would not have been known at all." We say, then, that the skilful ophthalmic physician must be a good pathologist, and that no man can write well on the eye without being thoroughly versed in the great general principles and practical details of medicine and surgery. Within the orbit is contained almost every variety of structure which is to be found in the anatomy of the human frame—bone, artery, vein, nerve, muscle, tendon, mucous membrane, glands, &c.—all subject to similar forms of diseased actions, and all amenable to the same general rules of treatment.

The first chapter of the work under review is devoted to "exploration" and the mode of "application of remedies": both are comprehensive and accurate. The instruction of delicacy of touch which this manual enjoins on students ought to be read by some of our professors of ophthalmic surgery.

On the causes of the accumulation and stagnation of the blood-corpuscles in the relaxed and dilated vessels we have the following doctrine:—

"When, then, the nervous influence is withdrawn from the small arteries, and they have in consequence become relaxed and dilated, and when any nervous influence which may naturally be discharged on the capillaries is from the same cause withdrawn, the blood flows slowly into the capillaries as into an indifferent cavity, and in the same condition, as regards tendency of the red corpuscles to aggregate, as blood newly drawn from the body, or extravasated, as well as with the same change in appearance.

"Aggregation of the red corpuscles accordingly takes place, some at the same time adhering to the walls of the vessels. The latter a phenomenon which is to be attributed in like manner to the suspension of nervous influence.

"The other cause—be it said dilatation of the paralysed vessels, referred to S. 180—of the retardation of the flow of blood now appears, from what has been above said, to be the commencing agglomeration of the red corpuscles, and the dilatation of the vessels, retardation of the flow of blood as a whole, as a fluid, is determined: the additional retardation by the commencing attraction affects the corpuscles only, hence their accumulation in increased quantity while the plasma passes on."

And on the mode of action of the exciting cause of inflammation we have this opinion:—

"Seeing that the essential condition of stagnation of the blood in inflammation is suspension of supply of nervous influence to the small vessels, the action of the exciting cause of inflammation must consist in producing this suspension.

"Section of some part of the sympathetic nerve appears to produce inflammation, by directly suspending the nervous influence from the walls of the vessels of the part."

Our limits will not permit us further to quote the reasonings and analogies of our author, who concurs in many of the doctrines of Henle, some of which, though not altogether demonstrable, have at least the claim of plausibility. We refer our readers especially to the sub-section of *Inflammation of non-vascular parts*, as illustrated in inflammation of the cornea, which are excellent. The whole chapter on "Inflammation" is interesting. We hasten without notice over the separate diseases of the eye,

the various forms of conjunctivitis, granular conjunctiva, serofulous ophthalmia, iritis in all its constitutional modifications, medullary fungus, staphylocoma of the sclerotic coat, melanosis of the eyeball, hydatid in the anterior chamber, dislocation of the lens into the anterior chamber, and cyst in connection with the iris—all of which are correctly described, and each delineated in a beautifully-executed coloured plate.

Purulent or Egyptian ophthalmia is considered by the author to be caused by infection in distans. We rather believe it to be produced per contactum. In Egypt the flies which swarm there carry the matter from the diseased to the eyes of the healthy; and certainly we think that gonorrhoeal ophthalmia is produced by accidental contact of the morbid secretion of the urethra. We think Mr. Jones is rather too fond of the laudanum in the purulent ophthalmia, as well as in the arthritic and rheumatic forms of iritis. In the latter we prefer soothing narcotic applications, the local application of belladonna, and a combination of the acetate with colchicum internally, in augmented doses. The paroxysmal pains can often only be subdued by morphia in full doses. Excepting in very rare instances, the less of the antiphlogistic treatment the better. In rheumatic affections of the eye being often preceded by, or associated with, general rheumatic pains, we find great advantage from the hot bath.

The chapter on "Cataract" contains all the most approved methods of operating. At page 247 we notice one error. "The only special preparation of the eye, previous to the operation for cataract, is the dilatation of the pupil." Not, surely, previous to extraction? for in that case the pupillary margin of the iris is in danger of falling in contact with the edge of the knife before the puncturation has been completed. In all other modes of operating, dilatation is absolutely necessary.

We congratulate Mr. Jones on having produced us a most valuable manual—a careful accumulation of all the information contained in almost all the best authors, foreign and domestic, and much original observation of his own. Besides the coloured plates, there are ninety wood engravings exhibiting numerous instruments and operations. For one who has not apparently enjoyed numerous opportunities of operating on the eye himself, we are surprised at the judicious selection of the best and safest methods, although, perhaps, he might have given some better modes of operating for strabismus. The volume will prove a valuable work of reference to the ophthalmic student, and to the practitioner.

The Pathological Anatomy of the Human Body. By JULIUS VOGEL, M.D. Translated from the German, with Additions, by GEORGE S. DAY, M.D.

(Concluded from p. 387.)

On the subject of pathological epigeneses, the observations of Professor Vogel are very numerous, and in the true spirit of sound induction.

"Pathological epigeneses," he says, "naturally divide themselves into two groups—the organized and the unorganized. The distinction between these groups is a double one.

"1. *There is morphologic difference.*—Organized bodies exhibit the same perfect form and internal organization throughout as in their separate parts, and as soon as they become parts of the organism. Unorganized bodies are devoid of organization, the highest and most perfect form they can assume being that of a crystal.

"2. *There is a genetic difference.*—Unorganized formations are always produced in accordance with the laws of pure chemistry, while organized formations follow the developmental laws of organic life.

"If, in perfectly normal formations, the difficulty in defining the limit between vital organization and mere chemistry, in pathological formations it is much increased, for each may be combined with, and indeed merge into, the other, so that in individual cases it is not always easy to determine to which group a formation belongs. This does not, however, hinder us from regarding the two groups

as representing opposite types. In their chemical compositions there are no essential differences, except that the organized formations consist, for the most part, of the substances known in chemistry as compound radicals; while the unorganized consist, in part, of inorganic matters, although compound radicals frequently also enter into their composition, and hence the terms *organic* and *organized* are not altogether synonymous in relation to morbid formations.

"Like everything else in nature, pathological growths require a material for their formation—a matter from which they may be produced. To this, which may be either fluid or solid, and may vary extremely in its chemical composition, we apply the general term *plasma*, or *formative matter*. It is a necessary character of this plasma to be amorphous; it must neither be crystalline, nor have a definite organic form. An already formed structure can only assume that function by throwing off its shape and becoming again structureless.

"A plasma may act as formative material either for organized or unorganized products, or for both at the same time. The plasma for unorganized formations, which is usually an aqueous solution from which deposits are produced or crystals formed in accordance with chemical laws, we shall name a *mother-liquid*, the matter giving rise to organized formations, which are chiefly produced by the formation of cells, we shall term a *cytoblastema* (*κύτος*, a cell; and *βλαστήμα*, a growth), or, for brevity, a *blastema*; and lastly, a plasma, from which organized and unorganized products are developed, will be designated a *mixed plasma*." (Pp. 100, 101.)

Our author is of opinion that "the production of many unorganized formations is dependant on the development of a new secreting organ, previously created by a morbid process. In illustration, we may mention the deposition of crystallized cholesteroline in encysted tumours, especially in that formed by Cruveilhier, the laminated nacreous tumour, where the deposition is so abundant that the whole contents form a connected and often tolerably firm crystalline mass." (P. 105.) We rather doubt the reasoning, or perhaps we should say the assumption, here. The fact of any material, say cholesteroline, being found in any spot remote from the liver is no proof of its having been produced in that particular spot, and by some newly-formed organism there. We are very much inclined to deny that the special product of any organ can be formed by any other than that said organ. Bile is sometimes found in the saliva, and in the tracheo-bronchial secretion: should we be justified in saying that the salivary glands in the one case, or a mucous membrane in the other, performed the peculiar function of the liver? Urea has been found in ascitic fluid, the issue of subacute peritoneal inflammation: did the peritoneum in this case secrete the urea? Cholesteroline has been found abundantly in fluid accumulation in the thyroid gland: was the cholesteroline formed in this spot, or only lodged therein? We opine the latter. So in the other cases, the distinguishing products of specific secretory function were rather separated from the blood into which they had been absorbed, than secreted from the elements of it. In the examples Vogel has mentioned, it is more probable that the cholesteroline was lodged in the encysted tumours, than formed within them.

Concerning the development of organized pathological formations, our author observes:—

"The development of organized morbid tissues is dependent on laws differing essentially from the chemical laws already considered. The difference is obvious even in the formative material. It is not every mother-liquid that can act as a cytoblastema for organized products. The cytoblastema is usually fluid; it may, however, be solid, but in this case it must of necessity be amorphous, that is, it must not exhibit either a definite organized appearance or crystallization. The only solid cytoblastema which has yet been noticed in relation to morbid products is coagulated fibrine in its amorphous condition and permeated with water,—in the state, for instance, in which it occurs in inflammatory exudations. But even this blastema was originally fluid, and only assumed the solid form on the coagulation of the fibrine. It is pos-

sible, although it has not yet been observed, that other protein compounds—albumen, casein, or globulin—may act when coagulated as cytoblastemata. In the production of morbid formations from mother-liquids, the plasma seems never to occur in the solid state; if, in the department of unorganized nature, as in chemistry or mineralogy, a crystalline formation can take place in a partially or entirely solid amorphous substance, as for instance, in iron, sugar, silica, &c. Nothing similar has yet been observed in the human body." (Pp. 105, 106.)

"When we have once established the principle that the blastema for morbid products must always be amorphous, the old idea is obviously overturned, namely, that a normal tissue may be directly converted into a pathological formation." (P. 108.)

We are glad to find our author speaking strongly on this point, as he does in subsequent chapters, to which we have not space to refer in detail. The notion here set aside is one of the errors of the earlier pathologists, who conceived that normal substances could be transformed into abnormal ones—that muscle, nerve, or bone, could relatively liquefy into pus, or become cancer or tubercle, or that these could pass into each other. Modern pathology, however, has shown the impossibility of these things, though there is one author who stands alone amid the march of modern enlightenment, and treats pathology now and then as though it had not made a stride for the last century: we allude to Dr. C. J. B. Williams, the President of the Pathological Society. At page 166 of the last edition of his work "On Diseases of the Chest" he gravely informs us that "*Lymph, pus, and tubercle, pass by imperceptible gradations into each other*!" The italics are the learned author's own. We have good reason to be grateful for the pathological information of our more trustworthy continental neighbours.

On the subject of the origin of cytoblastic formations, our author remarks:—

"In the present condition of our physical knowledge, I believe that no one will dispute with me, that we may establish the principle as a general law, that the cytoblastema of every morbid product, as also of the tissues in healthy nutrition, is obtained from the vessels, and that its source is always the blood, or, in some few cases, the chyle or lymph.

"In pathological epigeneses, it may often be directly observed that, in consequence of inflammation, the plasma exudes through the vessels and forms the cytoblastema; and in cases in which we observe no morbid secretion, it is more than probable that the ordinary nutrient fluid escapes through the vessels without inflammatory action, and thus forms a blastema for morbid products." (P. 109.)

The following observations, on a very important branch of this most important pathological subject, we have much pleasure in quoting:—

"The nature of the development of pathological epigeneses is dependent on—

"1. The cytoblastema, the quantity, quality, and mode of its production. The more rapidly and abundantly it is secreted, and in proportion as the chemical composition (which, however, is certainly not accurately known) differs from the normal blood—plasma, so does the influence of the surrounding histological elements decrease, and the formation proportionately deviate from the normal type. Thus, small quantities of exudation easily become organized, and simple hypertrophy usually consists in small exudations repeatedly occurring after long intervals (weeks or months). We can draw no very definite limit between this process and that of healthy nutrition. Abundant and rapidly formed exudations are rarely organized, usually proceeding to suppuration. . . .

"2. The nature of the development is influenced by the histological elements of the part in the epigenesis. If the influence of these predominates, the newly-formed material builds the pre-existing normal tissue, and thus, morbid hypertrophy, in regeneration of lost parts, &c., the process is just the same as in ordinary nutrition.

"The cytoblastema on the one hand, and the

pre-existing tissues on the other, are each factors influencing the formation of organized morbid products, and it is on their different properties that these epigeneses are dependent both for their mode of formation, and for their general characters." (Pp. 115, 116.)

We have only, in conclusion, to express our regret that we have not further space to devote to an analysis of this excellent work. It is really an inestimable gift to those who know the value of sound pathology, and desire to cultivate it. The volume is admirably put forth in its English character, and is enriched with plates that ably illustrate some of the more important points of pathology. We commend it, most earnestly, to the notice of all scientific practitioners.

SURGICAL SOCIETY OF IRELAND.

SATURDAY EVENING, Feb. 6.—J. W. CUSACK, Esq., Vice-President, in the chair.

Professor Benson read a communication from a country member, Dr. Vickers Dunne, descriptive of a case of ascites in a female, which after having resisted, during a long period, a host of remedies from the hands of nearly as many practitioners, at length disappeared suddenly, the rapid subsidence of the abdomen being accompanied with a profuse renal secretion. The woman was at the time using no remedies, but the occurrence was marked by slight restlessness and febrile symptoms. Dr. Benson thought the case had most probably been one of encysted ovarian dropsy, which gave way suddenly, as so frequently happens in those cases: the fluid being absorbed from the peritoneal cavity, and finally disappearing through the agency of the kidneys. Dr. Benson was the more inclined to this opinion, from the resistance to treatment of all kinds known to be so generally offered by cases of encysted ovarian dropsy, and their being also often known to burst from some trivial violence into the abdominal cavity, and the fluid got rid of in this way.

DISLOCATION OF THE FEMUR INTO THE SCIATIC NOTCH.

Mr. Bannan, of Jarvis-street Hospital, read the particulars of a case of dislocation as above: the subject, Lawrence Lawless, having been brought to the hospital on the night of the 6th of January, in a state of intoxication. In a quarrel with another man in the Custom-house, he had fallen from a loft about fifteen feet from the ground, and while down, and in a bent position, the other man fell on him. When assistance reached him he was unable to get up; he complained of intense pain and stiffness in the right hip; and such was his condition on coming under Mr. Bannan's observation at twelve o'clock at night. The right limb, accurately measured, was half an inch shorter than the left, with the knee and foot slightly turned inwards, the knee being somewhat advanced upon the opposite one. In the erect position, the great toe of the affected limb reached the ground and corresponded with the ball of the opposite great toe, precisely as described by Sir A. Cooper. The heel did not reach the ground. The knee could be slightly moved across the sound limb and rotated inwards. All other movements were impossible, and any attempt to make them gave considerable pain. The parts about the joint were tense, the trochanter major being prominent enough, but evidently placed behind its natural position; the distance between it and the anterior superior spine of the ilium was increased, as ascertained by measurement of both sides: a means of discriminating between this dislocation and that upwards, on the dorsum ilii, which Mr. Bannan referred to as important, the distance between these two points in the latter dislocation being diminished. The limb had, of course, lost its natural roundness; and, though the patient was rather thin, the head of the bone could not be felt.

He was at once placed on the table, and extension directed across the sound thigh, kept up for some time with Mr. Lestrangle's apparatus, at the same time that Mr. Bannan attempted for-

cibly to lift the bone over the edge of the acetabulum by means of a sheet placed under the upper part of the patient's thigh, and over his (Mr. Bannan's) neck, and pressing down the pelvis with his hands. All efforts at reduction on this occasion failed, owing, perhaps, to the struggles of the patient in his then drunken and unmanageable condition.

At ten o'clock next morning, however, he was again placed on the table, and extension for about twenty-five minutes had the effect of partly dislodging the bone from the deep bed in which it lay; nausea having previously been produced by four grains of antim. tart. The extension was now relaxed at an instant's turning by Mr. Hughes, who had charge of Mr. Lestrangle's simple and admirable apparatus for that purpose; while, at the same time, Mr. Bannan, assisted by Professor Harrison, raised the upper extremity of the femur over the posterior lip of the acetabulum, Mr. Woodroffe rotating the limb, and the bone re-entered into its socket with a loud snap. After three weeks in bed the man left the hospital free from any unpleasant symptom.

Mr. Bannan expressed some regret at not having known somewhat more of the effects of ether, at this time, not less on account of its great power in relaxing the muscles, than as a means of producing freedom from pain. He apologized for bringing forward the case, divested as it was of any new points; but yet, as the dislocation was one of rare occurrence, he thought a recital of the case might be useful to the junior members. Besides, it afforded him an opportunity of adding his mite of commendation to Mr. Lestrangle's admirable apparatus.

DISSECTION OF THE PROBOSCIS OF THE ELEPHANT.

Professor Harrison exhibited a dissection of this structure, made with much care and trouble, and felt great pleasure in laying it before the society, as opportunities of examining the anatomy of the elephant must necessarily occur very rarely in this country. It was only by the French academicians that any very accurate description of this curious and most useful structure had been published in the "Encyclopédie Méthodique"; Cuvier's description of it also has not been excelled by any more modern writer. Most persons were aware of the advantages of this structure as an organ of prehension, constituting, in fact, a sort of additional limb, by means of which this animal is enabled to seize and raise up food and drink to his mouth. Its importance for such a purpose is obvious, on looking at the position of the head, which, on account of its enormous weight, is tied up by a most powerful and unyielding ligament that prevents its being brought to the ground for the purposes of feeding, as in other animals. In strictly anatomical language, Professor Harrison observed, this organ is nothing more than a highly-developed nose, rudimentary traces of which exist in the pig and other animals.

In the elephant the upper portion, or true nose, is attached to the nasal bones and root of the frontal, whence it descends and is prolonged into the trunk or proboscis, which, like the nose, consists of two canals with a central septum, lined throughout by a strong membrane, of a whitish colour, and possessing but little sensibility; while in the true nose the membrane is highly sensitive and organized. The central septum runs the entire way, and is composed of a thick elastic substance; the proboscis ends in a thick lip-like projection, with a groove in the middle line below, and a knob-like projection above, capable of being moved about with as much facility as the finger in the hand of man. The trunk is composed of a thick rough skin, transversely wrinkled on its convex surface, with a prominent rugged ridge bounding each side of its inferior and flat surface. Beneath this is an amazing mass of muscular structure, commencing at the root of the forehead, or top of the nose, and running down the trunk in a longitudinal direction, being in fact, Mr. Harrison observed, a continuation of the occipito frontalis, or, as some call it, the pyramidalis nasi musculus. The fibres of these longitudinal muscular fasciculi are ex-

treely red and strong, the fasciculi themselves consisting of several layers, and forming a mass of great thickness. A second mass of muscles lies beneath this, but very differently arranged, consisting of a great number of short digastric muscles, beautifully and curiously disposed, forming tendinous sheaths for the various nerves, while the fleshy fibres run in a radiated manner to be inserted into the central tubes.

The nerves of this organ and their branches, consisting of the portio dura of the seventh, issuing from the stylo-mastoid hole, and the infra orbital branch of the fifth, emerging from the foramen of that name, are of immense size and number, constituting, he remarked, a greater mass than those of the whole human body would amount to. They interlace with each other very remarkably, much more so than the corresponding nerves of the human face, so that almost each fasciculus might be said to possess motor and sensitive filaments. Some of the latter, however, Mr. Harrison was enabled to isolate, and trace distinctly to their passages out from the head, without any interlacement as far as the tip. The tendinous canals formed, as described above, by the small digastric muscles, would appear designed to secure the former from compression during the action of the latter.

As before stated, the top of the trunk communicates with the true nose, the openings admitting of being closed, not by a perfect valve, as described by some, but the communication can be intercepted partly by the approximation of the lateral highly elastic cartilages, and completely by a lamina of muscular fibres which covers the membranous portion of each ala, which also contains a small cartilage.

The sensibility of touch of the tip of the trunk is of so delicate a nature that the animal can pick up the smallest bodies, such as even a grain of corn; at the same time that it is entirely destitute of the sense of smell, the olfactory nerves, which are of amazing size, being wholly distributed to the true nose.

A large flat pad of fibro-cellular and muscular substance is observed at the front of the head, a rudiment of which runs down the nose, and by means of which, and of his trunk, the animal performs those feats of physical strength that render him so useful in warfare and on other occasions. He can push with his forehead the largest of guns up steep eminences, or with his trunk lift them out of deep morasses, when they happen to become imbedded therein; by the same means he tears down large branches of trees for his food, or with his tusks uproots them from the earth. In drinking, the animal is observed to take the fluid, not directly into his mouth, but sucks it up into the tubes of the trunk, which, being closed above, he turns the trunk like the large spout of a jug into his mouth; the lower jaw and lip being shaped in such a form as accurately to receive the fluid. It has been thought that the young animal sucks the mother by similar means, and, from the difficulty of observing these animals with their young (as they seldom, if ever, breed in a state of captivity), this point was for a long time undecided. It has, however, he observed, been ascertained that the young animal presses close into the body of the mother, turns up the proboscis to one side, and holds the teat between the lower lip and margin of the trunk, and then sucks, occasionally compressing the udder with the proboscis, thereby assisting the flow of fluid into the mouth.

Reviewing the several characters of this appendix, viz.,—its conical form, great thickness, immense quantity of muscular tissue, its numerous nerves and vessels, the delicate sensibility and motor power residing in its tip, together with the central tubes,—all concur to render the proboscis of the elephant a very interesting object in anatomical and zoological science. It is a powerful weapon for offence and defence; an indispensable organ for the prehension of food; a refined instrument of feeling or of touch; while its thumb-like extremity is a delicate and dexterous motor agent. Its commu-

nication with the nose and respiratory passages enables it to raise up fluids and pour them into the mouth, and at the same time modifies its voice into the most varied tones, producing those well-known trumpet sounds, harsh and discordant, indicative of pleasure or of anger, so loud as to be heard at a surprising distance.

In conclusion, Professor Harrison promised, on a future occasion, to exhibit dissections which he had made of the ear and other parts of this animal.

TO CORRESPONDENTS.

A Surgeon, Brixton, thinks the spongio-piline is much too expensive ever to come into general use—21s. per yard; and suggests as a good substitute flannel, four or five or more folds in thickness, dipped into hot water, gently squeezed, and placed upon the part; over this, to prevent evaporation and consequently the heat escaping, a piece of Macintosh cloth, oil-skin (oiled silk), or, what is quite as good and can be got anywhere, a bullock's or pig's bladder, slit open and bound over all. Thus we have the two great requisites of a poultice, viz., heat and moisture, and at a much cheaper rate than spongio-piline.

An Old Subscriber (an army surgeon) having practised before 1815, cannot be molested in general practice.

A Student seeks to throw on us the responsibility of an advice, which we feel it our duty to decline. The Schools in their programmes tell their own tales with sufficient definiteness.

The philippic of Cato, being political and wholly unprofessional, would hardly bear publication in our columns. It would, too, rather serve than injure its object—who seems to be one of those persons to whom everything, short of the "extreme penalty" is luck. With regard to other parts of our correspondent's note, we refer for answers to our last number.

W. S. P. (Chester) will obtain, free by post, the Pharmaceutical Times and the Medical Times, for the ensuing four volumes, for £2.

M. D.—All the numbers of the last volume may be had.

H. S., on Mr. Cronin's case, is premature. This is not the moment when the relative blame of the different parties can be properly discussed.

Mr. Sebright's appeal to medical men, and to the members of the Army and Navy Clubs, should be published through some other channel. We may agree with Mr. Sebright, that our "risks and actual expenditure" achieved a public service, but still do not choose to make our journal the medium for appeals like those he proposes.

A Pupil.—At the College of Surgeons.

M. D.'s appeal is dictated by motives we appreciate, but we must decline its publication.

A General Practitioner sends us two guineas to what he calls "The Gratitude Fund"; "being two guineas for a post mortem examination, which, without the Medical Times, would have gone to Wilson." Our correspondent is informed that there is no such fund, and that his obliging contribution awaits his further orders.

RESULTS OF THE LATE LABEL ACTIONS.—As an evidence of the state of feeling roused by the recent illiberal and recreant endeavour to injure the Medical Times by trumpety, causeless litigations, we quote the following out of many assurances which have recently reached our publisher:—"I have hitherto (and for years) been a subscriber to the Lancet. I feel so much disgust at the editor of that periodical (from the oppressive conduct shown to the Medical Times, and his general treatment of the Medical Association, which is headed by Mr. Pennington), that I transfer my subscription from the Lancet to the Medical Times."

A. B.—The usual purchase-money of a practice are the net profits of two years. The amount, however, rises or falls with the peculiar circumstances of the practice and its prospects.

Mr. Blanch is quite correct in his observations, that rheumatic inflammation of the testicle has been noticed in a book published by Dr. Murphy, of Kensington.

The following communications are postponed to a future number:—

MR. SMITH, House-Surgeon to King's College, on the Action of Mercury in Inflammation.

DR. DAUNT, Clinical Notes, No. VI.

DR. CRYAN on Irish Medical Poor-Law Relief.

DR. WILLSHIRE, Clinical Observations on the Diseases of Children.

MR. HILLES on "Sudden Death."

MR. SOUTHER on Stricture of the Urethra.

MR. STARTIN on ULCERS and THEIR TREATMENT.

We have also to acknowledge communications from Dr. Bartholomew, Crail, N.B.; Mr. McCormack, Glenluce; Mr. H. P. O'Reilly, Dublin; Berridge, Melton Mowbray; O. Scintion, Edinburgh; J. Walkden, Blackburn; Deveny, Kellybegs; Monday, Olveston; Botham, Chesterfield; Hodgson, Egremont; Dr. Arnold, Atherstone; Mr. Chesterman, Banbury; Price, Swansea; Robinson, Monaghan; Fisher, Duncraig; Andrews, Bristol; Schofield, Manchester; Rolfe, Much Hadham; Murphy, Ravenhill; Bramley and Stanfield, Halifax; Helt, Washenburgh; Mr. Hare, Clifton; Sir A. M. Downie, Germany; Emmett, Hounslow; Green, Rochford; Hutton, Colford; Manchester Medical Society, Mr. Browne, Paignton; Purdon, Belfast; H. King, Colnbrook; Christie, Seaham; Rounth, Dublin; Hood, Newcastle-on-Tyne; Hooper, Kennington; Gibson, Ulverston; Shaw, Sutton Coldfield; Hutchinson, Bridlington; Lacy, Poole; Butler, Guildford; Buddell, jun., Tiverton; Dr. Lee, Northwich; Mr. Mudd, Stockport; Greene, Willington; Dr. Hamilton, Leamington; Mr. Barton, Ulverston; Mr. Goddard; Mr. Fisher, Bowdley; Shelton, Bromsgrove; MacLay, Glasgow; Mr. Bourne, Radstock; Thompson, Primrose; Counsellor, Gateshead; Nolan, Wicklow; and several other correspondents, whose favours we shall notice in a future number.

Mr. B., Marylebone, who courteously apprises us that he is already a subscriber, may possibly have a friend who is not, to whom the circular may convey a useful suggestion. Our circulation would be doubled, and the best of testimonials, secured us if those who think as favourably of us as our correspondent would make their convictions as widely contagious as possible.

Mr. D. T.'s case of ether inhalation has no peculiarities that can now make its publication useful. Our space is of no small value, and gentlemen who would use it, not to serve their brethren, but puff themselves, would do both an injury.

A. S.—There is no English book on infantile diseases that is really worthy of the present state of science. The clinical course our columns will owe to Dr. Willshire, physician to the Royal Infirmary for Children, will, we are in hopes, satisfactorily fill the void.

A Reader of the "Medical Times."—The diploma of the Glasgow Faculty will authorize medical practice in most, if not in all, our colonies. It is, we believe, the lowest-priced diploma in the kingdom.

Dr. Bushnan's work on the Water-cure has been received.

Specs asks us a question, which we could be an infraction of professional etiquette to answer.

Amicus Justitiae.—We are receiving, since the Hounslow inquest, so many letters detailing acts of coronatorial injustice to medical men, that we shall find it necessary in a future number to submit a scheme to our professional brethren, by which we may be enabled to teach those functionaries, that, with Lord Denman's judgment before the country, no further act of illegality and injustice shall go unpunished. The profession must be protected from what are nothing less than magisterial frauds, mischievous to the public, and oppressive to medical men.

A Student.—The work of Müller on Physics (perhaps the most perfect ever given on the subject) contains not 1000 engravings, but from 500 to 600. The Pharmaceutical Times, which this day publishes the second part of the work, gives in the present number no less than twenty-eight illustrations.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the SCIENCE of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract live of a pedantic and inapplicable lore. Every power of his mind is engaged; he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate, to be EXERCISED each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diploma or licence.

Six of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen and of whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital declaring that the writer is *bona fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, MARCH 6, 1847.

We last week dwelt at some length on the duties which the profession owes to the National Institute: we propose this week a few words on the duties which the Institute owes to the profession.

These duties take three aspects: one regards the profession—another, the public—a third, the Government; and all three are controlled, modified, and interpreted by the great final cause of the society itself, namely—its objects.

What are these objects? Briefly these:—to readjust medical polity by professional instrumentality. Medical agitation has taken many phases of years: it has combined; it has separated; it has publicly protested and petitioned; memorialized by hundreds, and assembled in thousands; it has played in turns assailant and defender; now humble and apathetic, now bold and energetic; but in all our changes there has been but one leading motor principle—the deep conviction that a great and severe change in our polity is indispensable.

Here, then, is the mission of the National Institute. Hence was it created—hence supported. The tenure not only of its prosperity, but of its very existence, is its efficacy in this service. As was said of old—"If thou wilt not labour, neither shalt thou eat." The Institute

exists for an end; and, that it may continue to exist, that end must be steadily, zealously, energetically kept in view.

Few, we imagine, think more highly of the Institute than ourselves. Few would make less unreasonable demands on its time and industry. None would more anxiously watch over its defence, or feel more pleasure in bearing testimony to its triumphs, and more than to these—its earnings. Still, regard no less for our duties than for its worth enforces on us the stubborn avowal:—*the council are not working hard enough.* Though their well-being be as dear to us as to themselves—were it possible, more so—yet truth and our very interest in that well-being extort from us the reluctant acknowledgment—that they are at this moment not up to the level of their responsibility. Like the soldiers of Hannibal, they are losing in the indolence of Capua the advantages gained by hard and steady fight at Cannæ. They are faithfully at their post, it is true—but they are not making the best or the most vigorous use of its opportunities. The important position—the great strength won in their arduous campaign—they are not turning to all the account of which it is susceptible. The generals of a victorious army, they are, in some measure at least, allowing it to disperse each man to his home—or waste its powers and energies in an inglorious and enfeebling inaction. We tell them this in time, while the mischief is neither great nor irreparable. We tell it to them publicly—that the *spur* may have a strength applied, not as by one—but by thousands. They have done good service; they are still capable and desirous of good service; and we have sufficient confidence in their honesty and good intentions to feel that they will yet thank us for enforcing on them an activity which must beget the state further good service. We desire to assure them that we are not unconscious of the value of what is often probably dinned in their ears—"prudence," "caution," and "leaving well alone"; nor are we unconvinced that there are times when it is wise "not to do to-day what can be quite as well done to-morrow"; but we tell the council bluntly, that theirs is not a to-morrow case—that theirs is not the position in which it is prudent to wait, wise to defer, or possible to leave "well alone." They do not exist to leave "well alone." Their charter to live is resistance to wrong, and the only result of inaction is to leave not right but wrong "alone." The source of their strength and virtue, as the first aim of their existence—is action. They are nothing, and must become nothing, without it. They have, for the present at least, no charter to administer; no corporate functions to fulfil, save this—to influence their brethren and the public in the active service of good government. The Institute, indeed, is not yet out of its infancy. It is not so much what it is, as what it has the power of becoming. It is a nucleus undeveloped: aggregating powers possessed, but not yet evidenced. The council have now scarce a duty save that of building up, widening, and strengthening the edifice. The profession has given them the materials to commence with; it remains with themselves to turn them

to full account. They are firmly established; safely, if not handsomely, set up; it rests with them to say with what success the business shall be carried on. But, having intrusted them with our "ten talents," we shall exact some day a rigorous account of their use. It will not do then to tell us that they have been unemployed, and that thus nothing has been either gained or lost. They are put out at usury, and the profession will insist on a handsome return for the trust.

The cardinal point of policy now is for the Institute to strengthen itself. Every thought ought to have this direction. It should construct itself into the largest organization into which it is possible, by the best policy and the most active exertions, now to form the profession. To this point all its meetings, publications, doings, and disbursements should tend. How acquire this extended support? There is one easy answer—"Go through the land, and show face to face to your brethren, as you may, that you deserve it." Be as active for union and good fellowship as your enemies are, against them. Beget zeal by evidencing your own: win confidence by demonstrating it deserved: the sacrifices you require in a public cause exemplify. There should be no town in England or Scotland unvisited by your truths and principles: and, once visited, there should be no town that should be left uninterested, unwarned, unenthusiastic to your cause. Collect medical men in each locality into a political *fasciculus* of power—ever ready to be wielded at an opportune moment, in a good cause, in concert with thousands of other *fasciculi*. Work first for all the practitioners: first secure and organize them—the public will be easy of attainment afterwards. These aims won—who shall doubt the enlistment of the Government? These not won, who shall doubt its indifference or estrangement?

There is here a mode of action as prudent as it is facile, which should not be delayed another week. Whatever the chances of the Institute with the Government now, they will indisputably not be lessened when a larger amount of professional support and interest can be evidenced.

The quality, indeed, which alone can present the Institute to the Government, as a negotiating power of not less consequence than the opposing corporations, is the zealous partisanship of a whole profession, evidenced by enrolments and pecuniary contributions. The Minister will always bow—indeed, always must bow—to so authoritative an intervention; and the profession would have in its own hands the materials, not less of its own reorganization than of its own defence and security. Whenever a Government settlement shall come, it is easy to foresee that one characteristic cannot be wanting—that that section of our body will have made the most concessions which shall have had least power to preclude them. In legislative houses, as elsewhere, the weakest will go to the wall.

THE CASE AGAINST MR. CRONIN.

We do not feel that it would be either just or decent to comment on this case before the jury

have returned their verdict. Whatever we might say would necessarily have the tendency to inculpate; and to prosecute without the functions or responsibility of that odious but necessary office, does not consist with the duty which we owe either to ourselves or our readers. The great distinction between this case and that at Hounslow is this:—That interference there, instead of pressing on the accused, defended, protected, and vindicated men cruelly and illegally aspersed, and against whom the prejudices of an excited jury, and the passion of an inflamed public, created dangers—and against respectable medical men—neither unreal nor unimportant. An interposition there by a medical journalist, with all the force which the magnitude of the occasion so loudly called for, was, as Lord Denman declared, of considerable influence. The coroner was checked in his inequality, the jury forced into comparative moderation, the public compelled to distrust the truth of their impressions; and hence that considerable influence was a public benefit—which fully justified an interposition which might, under other circumstances, have deservedly been deprecated. In Mr. Cronin's case the argument for indulging in comment is as weak, as in the Hounslow inquest it was strong. The man is on his trial for a very serious offence: his condemnation or acquittal should depend on the jury's view of the evidence adduced before them; and it ill becomes a medical journalist to take the responsibility of inciting to the inculpation of an unfortunate, if ill-doing, practitioner, by premature considerations which never ought to reach the jury but in one place, and that the court of justice—and through one channel, and that the witnesses.

We add, without one word of comment, that portion of the charge: the learned Recorder made to the grand jury, which has reference to this case:—

"There was, however, one case to which he should feel it his duty particularly to call their attention, because it was one a little out of the ordinary course, and, although the law was perfectly clear in reference to it, yet, as the evidence in such cases was ordinarily not very clear, and did not appear, indeed, to be so in the present instance, he thought it right to call the attention of the grand jury to the subject. The case in question was a charge against a medical man, of the offence of manslaughter, by the administering of improper and poisonous medicine, and thereby causing the death of the deceased. With regard to the question of medicine being administered by a medical man, or a person not licensed to act in that capacity, he must inform them that the law was clearly understood as not making any difference between persons so situated, and they were both equally amenable to a charge of manslaughter where death ensued, if the other circumstances, required by the law to prove the offence, were clearly established; and, therefore, the point whether the accused was a regular practitioner or not, would not require to be considered by them. The principal point for the consideration of the grand jury was, whether there had been gross negligence or inattention, such as amounted to a criminal disregard to the safety of life; and he must tell them that any proof of criminal inattention on the part of a medical man—there being, of course, no imputation of any deliberate intention to do injury—

would amount to the crime of manslaughter, where death was the result of such inattention. In a case of some notoriety, in which a gentleman named St. John Long was charged with manslaughter, the jury, by their verdict, specially found that he had no intention to cause the result that took place, but that still the death was attributable to a criminal disregard to the safety of life; and this was clearly held to amount to the crime of manslaughter. In the present case it would appear that the accused party did not actually administer the ingredient that caused the death, but, as it appeared perfectly clear that it was administered through him by an innocent agent, no difficulty could arise upon this point, and he would be equally liable, supposing the facts that were necessary should be proved to the satisfaction of the jury. (The Recorder then proceeded to state the circumstances under which the charge was made against the accused, and which, as they have been so very recently given, it will not be necessary to repeat.) He said, he collected from the deposition, that the accused had once before prescribed a similar medicine for the deceased, which was prepared under his own superintendence and control, and no evil result followed. On the second occasion, however, it appeared that he wrote a prescription, stating that the medicine might be made up at any chemist's shop; and this second medicine was alleged to have occasioned the death of the deceased. The prescription given by the accused referred, among other ingredients, to prussic acid of Scheek's strength, and also a certain quantity of compound strychnine powder, and bitter-almond water, which also it would appear contained a certain quantity of prussic acid; and he apprehended there would be very little doubt that the death of the deceased was attributable to prussic acid. If a medical man thought right to make use of such dangerous and deadly materials, it was undoubtedly his duty to take care that his prescription was properly and carefully made up, and it would be for the grand jury to look upon this as one ingredient in the case before they came to a conclusion that they had been gross or criminal negligence. It appeared that one ingredient mentioned in the prescription, viz., the compound strychnine powder, was omitted, the chemist not having that article in his possession; and it would therefore be a material question for the consideration of the grand jury, what was the character or quality of this material; and he recommended them, therefore, to question the medical witnesses particularly upon this point; as if it should appear that, although in itself a dangerous ingredient, yet that it was calculated to neutralize the dangerous and deadly qualities contained in the other materials that were prescribed, undoubtedly, in that case, the defendant would not be amenable to the charge made against him. The Recorder observed that he regretted he was compelled, in order to make the matter intelligible, to allude to the circumstances of the case with more particularity than he should have otherwise felt himself justified in doing, and to take for granted that certain facts would be proved; but the grand jury would, of course, only apply the observations he made to them to the evidence that would actually be produced, and to act upon that alone. They would first inquire into the cause of death, and upon this they would probably not feel any difficulty, and then the most important question would remain, whether the death was to be attributed to the prescription, not to the draught, he begged them to recollect, but to the prescription itself; and they would then inquire whether the article that appeared to have been omitted was of such a character as to affect the quality of the draught, or to render it more dangerous than it would have been if the medicine had contained that ingredient. Being satisfied upon these points, they would then see whether the facts warranted the assumption that there had been any criminal negligence, or disregard to the safety of human life, evinced by the accused. No man, medical or other, had a right to make use of such deadly

ingredients as those in question, unless under his own superintendence; and if he gave a prescription to be made up by an ordinary chemist, taking the chance of his doing so correctly, and of the fatal consequences that might result from any negligence on his part, it would be a question whether this would not amount to criminal negligence; and this observation would more particularly apply, when it appeared that two of the ingredients mentioned in the prescription were not mentioned in any pharmacopoeia. His lordship then made some further observations in reference to the nature of the case, and said that he had gone somewhat more at length than was his wont in his observations, because it was one of great importance; for, although it would be very hard to make a medical man amenable to a charge of manslaughter, because he happened to be unsuccessful in his treatment of any particular case, yet, on the other hand, it was necessary, for the protection of the public, that persons of the medical profession should understand that, if they chose to make use of dangerous and deadly ingredients, they were bound to exercise the utmost care and caution in so doing. The interests of science required that there should occasionally be some departure from the beaten path prescribed by medical authority; and many important results had followed from such deviations, by the alleviation of diseases heretofore deemed incurable. But, if dangerous experiments were attempted, the persons adopting them must be taught to keep within proper bounds, and that they must exercise the most ample caution in carrying out these experiments.

"The grand jury then retired."

TESTIMONIAL TO MESSRS. BIRD AND ANCELL.

WE are quite of the opinion of the Council of the National Institute, that some substantial token should speedily express the grateful and friendly feeling entertained by the profession to the late Secretaries of the National Association. They have worked well in critical times: devoted really high abilities and labours of no ordinary character, and accompanied by no small sacrifices in the service of a profession, whose interests were in no small danger. Hitherto their reward has been the vituperative and vindictive animosity of men offended by their honest zeal for the well-being of their brethren. It has, however, been well felt that it was neither right nor politic that this, however laudatory in its actual influence, should be their sole remuneration. No large community can ever be safe or prosperous, which has not in its body members who will fill the gap in a moment of sudden or imminent danger; and 'twould indeed be a vain hope to expect such opportune defence if the moment of our safety should not also be that of their appreciation. To deserve defence is to know how to value and to reward it: and we should despair not a little of the profession's future, not less than of its deserts, if such toils as those of Messrs. Bird and Ancell should go unrewarded and unacknowledged.

FATAL ETHER OPERATIONS.

THE case of lithotomy performed at the Suffolk and Colchester Hospital, proved fatal within twenty-four hours after the operation. We understand also, that an old gentleman operated on for some disease of the foot during the last week, by Mr. Travers, died within twenty-four hours of the operation. He never recovered from the stupor caused by the ether.

MISCELLANEOUS CORRESPONDENCE.

LETTER FROM MR. CLAY.

Manchester, Feb. 17.

SIR,—The answer to my charge against you "of attempting to palm upon the world, as a discovery of your own, the treatment of varicose veins with Vienna paste," is still *unrefuted*; and your subterfuge of turning the subject to a translation of a book, which I neither mentioned nor thought of, will neither do for me nor the profession at large. I told you the facts and cases of Laugier and myself were published in the *Lancet*, and, I may further add that Laugier's remarks were copied in most of the European medical journals, where you must have seen them, although I suppose you thought the facts were forgotten, and you might now claim the discovery as yours. I challenge you to produce a single case publicly attested where the Vienna paste was ever used for such a purpose in England by yourself, or any other person, prior to 1839, simply because the idea was unknown to the profession before Laugier announced it. Had the governors of St. Bartholomew's Hospital elected their medical officers by *concours*, I think the name of Skeg would have been omitted amongst the *assistant-surgeons*. See *Medical Times*, vol. V., p. 89:—"On small men we will be mild: they got their places, like their principles, by interest. Skeg is middle-aged, &c. &c., has written on ulcers and syphilis, a critique upon which thus expresses itself—'Six or seven lectures bound together make a book.'"

Hoping a more honourable course may guide you in future is the wish of,

Yours respectfully,

CHARLES CLAY, M.D.

To T. C. Skeg, Esq., Grosvenor-square, London.

A SUGGESTION.

[To the Editor of the Medical Times.]

SIR,—Experience has taught me that the most simple contrivance for the effectual and safe administration of ether by inhalation is to saturate a sponge with the following ethereal solution, and apply it to the mouth and nostrils, so that the patient may breathe easily through it. The ethereal solution which I recommend, and which, from its less irritating and more sedative properties, I have found to answer better than either sulphuric or chloric ether alone, is prepared by adding two drachms of ethereal oil (ol. æthereum) to six ounces of pure rectified sulphuric ether. I have now administered the ether in more than forty cases, and have tried a variety of apparatus, but am persuaded that the above is the cheapest, safest, and best.

This morning, Mr. Tibbs, surgeon-dentist, extracted three teeth, without causing any pain, from a patient, Jane Richards, residing at No. 6, Ortel-place; and the effects were kept up for nearly three quarters of an hour, by the continuous applications of the sponge, without the slightest unpleasant after-consequences. Mr. Fricker (surgeon) and Mr. Perry were present, besides Mr. Tibbs and myself, and expressed themselves highly gratified with the result.

I have the honour to be, your obedient servant,

THOMAS SMITH M.D.

Portland-house, Cheltenham Feb. 15.

[To the Editor of the Medical Times.]

SIR,—In your last number (I have not seen the previous number) you have introduced the concerns of the Edinburgh Infirmary. Permit me to tender a brief explanation.

Soon after the silly and very shameful *doquet* tomfoolery was inflicted upon the Annual Court, I attempted to check the irregularity; but the Court put me down. Then and now I was convinced that the question introduced was no question proper or even ripe for examination of that court, being purely a question between superior servants and one

inferior servant. In railway questions, I am told, it is a common reply with Mr. Hudson, when a similar complaint is made to him, "Oh, Sir, I never meddle with these things; go to Mr. So and So; he has the entire charge of that department of the railway, and he has my thorough confidence." When the Infirmary Annual Court was applied to, in precisely similar circumstances, on a question distinctly between the managers and a servant of the infirmary, but most particularly when this servant rebels most despitely, and glories in his rebellion, against their implied mismanagement, this Hudsonian answer should have been returned, even to the President of the Royal College of Physicians—the volunteer complainant—"Go, Sir, with your complaint and all your mental reservations, to the managers of the Royal Infirmary of Edinburgh. They have the entire charge of that department in the infirmary, and they have the thorough confidence of this court."

A few days after this *soderunt*, I found in the Edinburgh newspapers Mr. Syme's remarkable epistle, which you have also printed, addressed to "My lords, ladies, and gentlemen of the Edinburgh Infirmary Annual Court." With "the formidable rival infirmary, which had sprung up at the door of the Edinburgh Infirmary"—with his "deanship"—I have no concern whatever. With his professorship—a demon's scourge cruelly placed in his hand—with his correct or incorrect conduct as a surgeon in the Royal Infirmary of Edinburgh, and with the surgical patients located in his wards there, whom, till now, I always believed to be *his* patients—with these I have a deep concern, and hold him, even to me, responsible.

That remarkable document informs me that the deeply responsible duty of attending to the surgical treatment of *all his* infirmary patients daily occupies one hour per chronometer; and that medical students, for twenty-three hours out of the blessed twenty-four hours, are the daily surgeons of *his* infirmary patients.

For example: A patient with a fractured limb is brought into the infirmary at two o'clock P.M. It is a medical student who examines the accident at the time, and applies the bandages. This alone would be abundantly cruel—but the medical student is seldom *solus* in this cruel case:—the *corps* denominated clerks, and the legion of medical students around the sufferer, interrogate, examine, confound the victim—and inflict that second examination described by Mr. Syme in his letter as an examination "which can never be made without causing pain, which should have been carefully avoided, and tends to delay the healing process, besides exposing the patient to the risk of more serious consequences." In this deplorable condition, the wounded man lies, until Mr. Syme—his nominal surgeon—visits the infirmary *next day at noon*, when the bandages must be again opened for Mr. Syme's information, and nature's operations, at a most critical period, interrupted.

But this victim with a fractured limb is not a solitary example of Mr. Syme's surgical attention to patients in the Edinburgh Infirmary. He formally certifies to the lords, ladies, and gentlemen of this infirmary annual court, that no patient located in his wards, whatever the case may be, receives from him (the surgeon) daily more than an arithmetical fractional portion of one hour's surgical treatment; and the whole of the *doquet* mystery is wrapped up in this handkerchief. An infinitesimal dose out of sixty minutes gives a soft quietus to all "his various engrossing cares attendant upon an hospital visit!"

I have witnessed, while a member of this infirmary annual court, two calamities:—

1. Mr. Liston—stuck up in a corner of the court, denounced in very extravagant terms, by the President of the Court of Session, as the surgeon who cured all incurable diseases—expelled from the infirmary.

2. Mr. Syme—not indeed personally present, but through the press, and the mouth of the president of the Royal College of Physicians—at-

tempting to evade a pledge to obey a command which all other professors obeyed, pleading that his infirmary patients are not *his* patients; boasting that only for one hour daily they receive an infinitesimal dose of his attendance and care; confessing that for twenty-three hours daily they are the devoted patients of medical students; threatening to resuscitate his "formidable" opposition infirmary; and, to crown all, proclaiming defiance to the authority of his employers, the managers of the Royal Infirmary of Edinburgh.

These managers he has indeed humbled, for he has demonstrated as plainly as language can express any demonstration, that the pretence of charity or benefit to the infirmary patients, from the connection of the infirmary with what is as ludicrously as mischievously denominated a medical school, is only equalled by the pretence of benefit to the youths, misnamed students, who are compelled to waste their time and money, as much to their own serious detriment and degradation, as of the hapless patients, whose peace and feelings and recovery they so cruelly and preposterously and unwarrantably and unnecessarily diminish and retard, and too often destroy.

So long as I am certain that nothing but injustice, cruelty, mischief, and confusion can result from the combination of an infirmary and a medical school, I shall, in season and out of season, stigmatize such an unholy union, and shall leave no stone unturned, as well for my profession's as for humanity's sake. I shall put forth every effort to cut the Gordian knot—to establish a pure infirmary. Language cannot express the atrocity of mounting such a Nemesis as a medical school is, upon the back of an infirmary. Men may call the noble Arabian steed, which bears the savage Tartar into the field of carnage, a lamb. Call the noble animal what you may, he is a destroyer—his hoof, indiscriminately, without regard, tramples, mangles the peasant and the prince—man, woman, and child.

The extinction of such atrocities can never be effected by poking about the circumference of the circle. It can only be effected by a bold powerful blow struck at the centre—the Royal Infirmary of Edinburgh.

I am, Sir, your obedient servant,

JOHN THOMSON, M.D.

York-place, Edinburgh, Feb. 23.

DR. HILBERS'S REPLY TO DR. ORPEN.

[To the Editor of the Medical Times.]

SIR,—As I am so directly addressed by Dr. Orpen in his letter on homœopathy, I feel constrained again to trespass on your liberality, lest my silence should be misconstrued. It is with some reluctance that I do this, because, when I wrote my former short letter, I endeavoured so to frame it, that while it answered the purpose for which it was written, I might escape the necessity of replying to any further attacks on the system proceeding from the same quarter.

I think the easiest and most direct way of pointing out wherein Dr. Orpen's experiments were faulty will be to relate the manner in which Hahnemann obtained the vast body of symptoms which he describes in his "*Materia Medica Pura*," as being those which the different medicines will produce on the healthy human organism. I feel the less regret at occupying the valuable columns of the *Medical Times* with this subject, because it is one of great importance; and one which is engrossing the attention of some of the most celebrated philosophers in the *allopathic* schools of medicine on the Continent; and even in our own country examples are not wanting of those high in repute in the medical world inculcating on the profession the necessity of their studying the pure physiological effects of medicines on the healthy body. In Germany the rancorous animosity once exhibited towards Hahnemann and his system is happily dying away, and the authenticity and value of his researches in this branch of medical science are now openly acknowledged by some of the most celebrated teachers of thera-

patients, who do not hesitate to recommend to their classes the "Materia Medica Para" as the best work extant from which they may obtain the requisite information.

A twofold source furnished Hahnemann with the recorded symptoms:—1. He diligently sought out, in the writings of his predecessors and contemporaries, for the various morbid phenomena which appeared in those cases where poisonous doses of the medicines had been taken. These he carefully collected; with his wonted accuracy, affixing to each symptom the authority from whence it was derived. His great learning, and prodigious powers of research, well qualified him for the efficient performance of such an undertaking; and thus he obtained many of the most characteristic peculiarities of the different medicines. 2. He took himself, and administered to others, daily, doses of the medicines, carefully noting down from day to day the effects produced on the different "provers." The precautions which he deemed necessary to ensure correctness in these "proving" are to be found detailed at length in the "Organon," sections 120 to 140 (fourth German edition). Space does not permit me to transcribe them at length, nor is it of material consequence, as the only point we have here to consider is the dose in which the medicines were taken, and the preparations which were used. Section 121 runs thus (American translation):—"In studying the effects of medicines upon healthy persons, it must not be forgotten that even the administration of moderate doses of the so-called heroic remedies is sufficient to produce modifications in the health of the most robust individuals. Medicines which are more gentle in their nature ought to be given in larger doses, if we would likewise prove their action. Finally, if we would prove the effects of the weakest substances, the experiment must be made upon persons only who are, it is true, free from disease, but who are at the same time possessed of a delicate, irritable, and sensitive constitution." In other words, the doses varied (as I said in my letter) according to the commonly received opinion as to the medicinal activity of the substance. To guard against injurious consequences, the prover began with a small dose, and daily increased it. In section 123 the mode of preparation is described. Indigenous plants are to have their juices expressed, and are to be mixed with a small quantity of alcohol. Foreign plants are to be pulverized, or prepared as spirituous tinctures, and are to be mixed with a certain quantity of water before being taken. Salts and gums are to be dissolved in water just before being taken. An infusion of dried plants is to be made with boiling water, which is to be taken whilst warm. A different mode of preparation was employed for those substances, which possessed no apparent medicinal properties in their crude state, as the metals, calceare, sepiæ, vegetable carbon, &c. &c. These Hahnemann directed should have their properties developed by trituration. One grain was rubbed for many hours with five, ten, twenty, or a hundred grains of sugar of milk, and the "prover" was to keep on increasing the dose till symptoms appeared. The "proving" of such substances are to be found for the most part in the work on chronic diseases.

For many years Hahnemann contented himself with the provings thus obtained, but in his later days, after he had announced his discovery of the "theory of potencies," he began to use the infinitesimal doses in the provings of some few of the medicines, not *alone*, but in addition to his former plan. If any abnormal sensations appeared when the prover was taking the infinitesimal doses, they were set down as having been occasioned by these doses; but if none such appeared, he went on to the increased dose as formerly. This theory of potencies, as well as the Psoric theory, was, both at the time of its promulgation and since, disbelieved by many of the most celebrated homœopathic practitioners. A belief in it is not in any way essential to the practice of homœopathy, and it is manifest that, even allowing that Hahnemann was in error in believing that these minute doses were capable of producing medicinal symptoms in a person in health, the authority

of the *Materia Medica* would be but slightly impaired: for the symptoms obtained from this source only formed the smallest possible minority of the aggregate number of symptoms. Then, as no homœopath thinks of prescribing on one symptom alone, it is but of slight importance whether these symptoms are or are not genuine. Attempts have, however, been made to purge the work from these uncertainties.

From this statement I think it will be evident even to the meanest capacity, that Dr. Orpen's experiments with the infinitesimal doses *alone* are utterly insufficient to justify him in asserting that all Hahnemann's provings (to obtain which, he remembered, entirely different means were used) are the mere inventions of his brain; or, as he less politely terms it, enormously lying and deliberate humbug. Before he could do this he ought carefully to have repeated all Hahnemann's experiments, and not to have invented experiments of his own (the italics are verily mine); and I will undertake to say that Liebig and Berzélius, and the shades of Sydenham, Lavoisier, and Co., if they could speak, would bear me out in saying, that if an author declares that a certain number of causes lead to certain effects, it is necessary, before these effects can be reasonably denied, to put all or the greater number of these causes into operation; and that it is the height of imbecility to say that, because in one single instance one single set of experiments has failed, therefore, that an immense body of facts, founded on an entirely different series of experiments, are false.

I will now endeavour, as briefly as possible, to reply to the numerous questions he has put to me in the order in which they occur; but he will observe that many will have been already answered in the preceding statement. My reply, then, to the first three questions contained in the second paragraph of his letter is, that after a most diligent search I am unable to discover any sentence, or part of a sentence, in my letter which the most perverse ingenuity can torture into a plea for putting such questions to me. If I were disposed to hazard an hypothesis in the matter, it would be that Dr. Orpen had been amusing himself by transposing my words in the same way that they do letters, to form anagrams, and that thus he had obtained the requisite materials. He will, without difficulty, I should think, be able to discover that, in my opinion, they should all be answered in the affirmative.

I am not aware that Hahnemann ever said that the effects of an infinitesimal dose of medicine, taken by a person in health, would display its effects for six weeks. Will Dr. Orpen refer us to the work where this assertion is made? It is quite true that the use of tobacco was permitted to the "provers" during the time that they were taking the medicines—the reason for this is obvious. The Germans are from childhood so habituated to its use, that it soon ceases to have any medicinal effect at all on them. Hahnemann's object would have been entirely defeated had he forbidden it, because the leaving it off would have excited as many abnormal phenomena as total abstinence from food and drink. Every smoker knows the extreme inconvenience occasioned by breaking through the habit when once formed.

Neither I myself, nor any homœopath with whom I am acquainted, has ever been so silly as to confine our experiments with the homœopathic medicines, for the purpose alluded to, to the infinitesimal doses. But societies are being formed all over the world for the purpose of re-proving the medicines, in order to correct or corroborate Hahnemann's provings. The plan generally adopted is as follows:—The secretary gives to each member a medicine prepared in accordance with the rules already specified, without telling him the name of it. At the next meeting each member appears furnished with a list of symptoms which the medicine has produced. These are then compared with the "Materia Medica," and the result in general has been to confirm, in a most wonderful manner, the accuracy of Hahnemann's observations. Did space permit I could give some striking illustrations of the truth of this assertion.

Why my "theoretic illustrations" from musk, &c., should be judged to be an absurdity on the

first two counts, I cannot exactly see. I am also at a loss to imagine how Dr. Orpen can assert so positively that the experiment was never made. As far as my memory serves me, I read the statement in "Chambers's Edinburgh Journal" some eight or ten years since, but, as I have not the numbers by me, I am unable to refer to them. If the belief "that effluvia is in any case produced by a continuous waste of particles issuing from the odorous body and impinging on the nervous expansion for smelling" is an absurdity, I must assuredly plead guilty, for I verily believe it to be so. To alleviate the shame, however, which I might otherwise feel, I have the consolation of having for my companions in my absurdity many eminent physiologists, including Sir C. Bell, Müller, and Dr. Carpenter. Sir Charles says ("Anatomy and Physiology," vol. iii., p. 206)—"Animal and vegetable bodies, during their life, growth, putrefaction, and fermentation, and most probably all bodies whatever, are perpetually giving out effluvia of great subtilty. Those volatile particles repelling each other, or diffused in the atmosphere, are inhaled by the nose, and convey to the pituitary membrane the sensation of smell." Müller says ("Elements of Physiology," p. 1312)—"The material causes of odours are, in the case of animals living in the air, substances suspended in a state of extremely fine division in the atmosphere." Dr. Carpenter says ("Manual of Physiology," p. 560)—"There are some solid bodies which possess very strong odorous properties without losing weight in any appreciable degree by the diffusion of their particles through the air. This is the case, for example, with musk, a grain of which has been kept freely exposed to the air of a room, whose doors and windows were constantly opened for a period of ten years, during which time the air thus constantly changed was completely impregnated with the odour of musk; and yet at the end of that time the particles was not found to have perceptibly diminished in weight. We can only attribute this result to the extreme minuteness of the division of the odorous particles of this substance." Will Dr. Orpen give us equal authority for a contrary opinion? If not, however heterodox my opinions in therapeutics may be considered, I must at least advance a claim to superior orthodoxy in physiology.

From the next paragraph I think we may fairly deduce what I have long suspected, that Dr. Orpen's experiments were not undertaken with any *bona fide* intention of elucidating truth. Had they been, he would not have rested satisfied with attributing to fancy any abnormal sensations which he might have experienced immediately after he had taken the medicines. A true philosopher would have repeated the same experiments again and again, until he had satisfactorily ascertained whether such sensations were real or accidental.

Judging from the next paragraph, one would imagine that he had never heard of such things as persons being poisoned, and *post-mortem* examinations following on their death. If he doubts the capability of medicines to produce effusions into the cavity of the brain and its membranes, I would recommend him to study "Christison on Poisons," and the section headed, "Pathologische Anatomie," affixed to each medicine in "Nosok and Trink's Handbuck."

The "pretty quotation" from Harvey was made, not because I desired to attribute any particular virtue to the name, but because I thought it was the only decent way in which a gentleman could notice the coarse abuse so lavishly bestowed on a body of men, at least Dr. Orpen's equals in probity and honour, and many of whom are immeasurably his superiors in learning and scientific attainments. He must permit me to tell him, that, however gratifying such language might be to the readers of a third-rate Sunday newspaper, it is but little suited to the refined tastes of the more enlightened members of the medical profession, for whose benefit I presume the *Medical Times* is weekly published.

If I were called on to give an illustration of my ideas of the very essence of "humbugology," I do not know that I could find a more apt one, than when one writer deliberately misstates the words of another. I must leave it to my readers to decide whether

Dr. Orpen has done this in the following paragraph—He says, that I "argue" that medicines will cure a person diseased, because marsh miasm will produce again. Where do I do this? My words are, "I offer these suggestions, not in order to prove the efficacy of the homœopathic medicines, but to show that it is not utterly impossible that these globules can have any medicinal action." And I give as my reason for doing this, that I myself was often led into careless prescribing, during my novitiate, from being strongly impressed with an opposite opinion. The next paragraph is almost as great a perversion of my meaning. What I said was, that the illustrations showed that the animal fibre was so delicately constituted that it is capable of being affected by particles of matter more minute than the highest homœopathic attenuations. This is a fact so notorious that I am surprised that any one in his sober senses should cavil at it. But I never said that the organism was capable of being influenced at all times, by all minute particles of matter indiscriminately. I believe that it requires a peculiar susceptibility to exist, or be excited, to peculiar particles of matter, before abnormal phenomena appear. We know, for instance, that an individual may reside for a length of time in a marshy district, without an attack of fever, and yet, if his bodily health be disarranged by mental or physical causes, he may at length fall a victim to it. So with the homœopathic medicines. A person in health may take a great number of those of high dilution with impunity, and yet if, from disease, a peculiar susceptibility is excited to any one of them, I know from experience that that medicine will powerfully affect the organism. As a homœopathist, I believe that this susceptibility is regulated in accordance with the law of *similia similibus curantur*.

Among the many weak and foolish arguments which are brought against homœopathy, that derived from the supposed changes in it is the weakest. Homœopathy in its essence remains unchangeable and unchanged. In its details, it is true, the disciples of Hahnemann, claiming the privilege of thinking for themselves, do not consider that they are at all bound to follow him blindly as their leader, and thus, in minor matters, they in some instances dissent from his opinions, when experience tells him that he was in error. But, so far from this being a proof that homœopathy is false, I know of no stronger argument which could be brought against the system, none that would so surely have stamped it as false and useless, than if it had been said that it remained the same in every particular, after half a century of experience, and that time had failed to detect a single error in the minor hypotheses of its founder. History might have been ransacked in vain to afford an analogous instance. It would have stood forth solitary—alone opposed to every former precedent. But I can assure Dr. Orpen, that never at any moment has the flame burnt so brightly, or diffused its vivifying rays so extensively, as at the present time. There is not a civilized country under heaven that is not illuminated by its beams, and even on the inhospitable western coasts of Africa it has extracted the sting from that fatal fever which has hitherto defied all human means which have been tried to conquer it.

I now come to the concluding paragraph of Dr. Orpen's letter. Did it rest with me, every medical man in Norwich should at this moment be experimenting with the medicines, gladly would I supply one and all of them with the requisite materials, and give them the best advice in my power as to using them. But unfortunately the "go-ahead" principle is not so fully developed here as it is in Birkenhead. The inhabitants of the eastern counties have from time immemorial been slow in accepting untried novelties, and I therefore fear, and indeed know from experience, that it would be a more difficult matter than perhaps he imagines, to persuade any of them to undertake such experiments as he suggests.

In conclusion, I advise him to repeat his experiments on his own person, and on other healthy subjects among his friends, and to do so, not in a way of his own, but in the way Hahnemann

directed these experiments should be made. Let him diet himself, or others, strictly for a week before he begins a medicine, let this be taken in the prescribed doses, not in minute or infinitesimal ones, and let him gradually bring the dose up to the heroic standard of his own school. Then let him try the effects of the infinitesimal doses on disease; let him do as I did, and resolutely determine never to rest satisfied until I had sifted the matter to the very bottom; let him, as far as possible, put all his patients for the next six months under the homœopathic treatment, continuing the experiments for twelve or twenty-four hours in acute, for a longer period in chronic, diseases, of course always excepting those who he thinks likely to suffer from any delay in applying his own remedies. Above all things, let him not allow his scepticism to lead him into the performance of inconclusive or absurd experiments, and let him be careful always to prescribe the proper homœopathic remedy, and also to keep notes of all the cases he attempts so to treat. These were nearly the same rules which I laid down for my own guidance, when I was as sceptical as Dr. Orpen. Finally, I recommend him to study the "Introduction to the Study of Homœopathy," by the editors of the "Homœopathic Journal," and also diligently to attend the Homœopathic Dispensary, at Liverpool, where he will see 300 patients treated weekly. I will ensure him a courteous reception from the two physicians at the head of that institution, and he will find that a careful observation of their practice will materially assist his own. If, after he has done all this, he gets no results in conformity with those of Hahnemann and the homœopathists, he may fairly come before the public and denounce the master as an impostor, and the disciples as dupes or rogues. Let him meditate on the aphorism of Lord Bacon—"Believe nothing on credit, reject nothing on improbabilities." Perhaps, then, however impossible it may now appear to him, a really honest inquiry may end in Dr. Orpen's enrolling himself in the ranks of the homœopathists.

I am, Sir, yours obediently,
GEO. HILBERN.

REMOVAL OF THE GREAT TOE AND PART OF THE METATARSAL BONE, UNDER THE INFLUENCE OF ETHER.

By J. HERBERT BARKER, M.D., M.R.C.S.

Emma Rawlin, aged twenty-three, of Coptham, near Bedford, had been labouring under intractable strumous disease of the great toe for the last five years, involving the phalanges and part of the metatarsal bone, and was anxious to have the disease removed by operation. Desirous of giving her the benefit of inhaling the vapour of ether, I procured the apparatus constructed under the directions of Dr. Boott and Mr. James Robinson, and sold by Mr. Hooper, of Pall-mall, London, and yesterday removed the diseased parts in the following manner, with the kind assistance of Mr. Hurst, and in the presence of Messrs. C. W. Hynes, W. Bailey, Anthony, Birch, Cox, and Ravenscroft.

Having succeeded in about four minutes in getting her thoroughly under the influence of the vapour, a flap of good size was made with a scalpel on the inner side of the foot, the metatarsal bone being laid bare to beyond the extent of the disease. A strong bistoury was then passed through the space between the metatarsal bones of the first and second toe, in close contact with the former, and brought out anteriorly; the flexor and extensor tendons were divided, and the metatarsal bone nipped through with Liston's forceps; the exposed surfaces were sponged, and the flap secured by three points of interrupted suture.

During the operation, which lasted but a short time, the supply of vapour was cut off by means of the stopcock. She did not in the least shrink from the knife, nor did she manifest in any way the slightest sign or expression of pain. On regaining her consciousness she inquired when the operation would commence, and, on being told that all was over, stated that she had been asleep and dreaming.

The testimony of so many operators has already

been recorded of the efficacy of the inhaled vapour in completely destroying the sensibility of the system during severe and protracted operations, that there cannot be a doubt that this is one of the greatest discoveries of the age, productive as that age has been of great discoveries.

I thought it desirable that my patient should be previously tutored in the process of inhaling, and for that purpose induced her to inhale the vapour the day before the operation, which she did to the entire satisfaction of both of us. This appears to be a matter of some importance, and likely to contribute to the success of the process, inasmuch as there are several precautions which are better to be thus explained beforehand, and the patient will be less likely to be harassed with unnecessary timidity at the time of the operation.

The points which appear to require particular attention are—

1. To tutor the patient beforehand in the process of inhaling, and in the great majority of cases this will be practicable.

2. To give charge of the inhaling apparatus to a trustworthy assistant, who should keep the mouth-pad in firm contact with the lips.

3. To allow two or three inspirations to be made before removing the small stopper and applying the nasal spring, otherwise the full volume of the vapour will be likely to excite coughing and a sense of suffocation.

4. To cut off the supply of vapour for a time by turning the stopcock and removing the nasal clipper, when deep insensibility has been produced.

The moral effects of the inhalation of ether have yet to be made out, and good service will be rendered to the profession and humanity by any one who will investigate the precise effects of this powerful agent when administered in cases complicated with pulmonary, cardiac, or cerebral mischief. Some affections of the heart, and strong predisposition to cerebral disease, will probably be found to be the morbid conditions more particularly contraindicating its employment.

Bedford, Feb. 16.

ST. BARTHOLOMEW'S HOSPITAL.—TESTIMONIAL TO JOHN P. VINCENT, ESQ.

On Monday evening, the 1st instant, a public meeting of the pupils and friends of Mr. Vincent took place at St. Bartholomew's Hospital, for the purpose of making arrangements for offering him some testimonial of their respect and esteem upon his retirement from the surgery of the hospital. The meeting was numerously attended, and Dr. Roupell, being unanimously called to the chair, very ably addressed the meeting, setting forth the claims of Mr. Vincent to their love and admiration, and pointed out the matters which it would be necessary for the meeting to consider in order to the efficient carrying out of the object they had in view.

Mr. Brownless then rose to propose the first resolution—"That a testimonial be presented to J. P. Vincent, Esq., upon his retirement from the office of Surgeon to St. Bartholomew's Hospital"—and spoke as follows—

Mr. Chairman and Gentlemen,—If I should content myself with simply moving the resolution which I have just read to you, without offering my humble but most sincere testimony of the high estimation in which Mr. Vincent has been and is held by the pupils past and present of this hospital, not only from his great surgical attainments, but also for his ever honourable conduct and urbanity of manner,—if I could sit down without making some acknowledgment of his uniform affability, and of the admirable lessons in practical surgery which we have all more or less received at his hands,—I should indeed be wanting in gratitude, who have witnessed for so long a period his great abilities and many virtues, who have partaken so largely of his kindness and valuable instruction. I think, too, that I should be failing in duty to many of my old friends and fellow-pupils at this hospital who are now scattered over distant parts of the globe, if I did not come forward on the present occasion to testify, on behalf of them as

well as of myself, to the universal feeling of admiration and respect which Mr Vincent has secured to himself by the manner in which he has ever discharged the arduous and responsible duties of the office from which he is now retiring. Nor are the praises of Mr. Vincent proclaimed by the pupils only of this hospital: for, whilst we have admired his singular tact—his acute perception—his most accurate diagnosis and successful treatment of disease, his poor patients have not failed to appreciate his kindness of manner and humane disposition. (Loud cheers.) Most highly is he esteemed, and deeply indeed is his retirement lamented, by every class of persons connected with St. Bartholomew's Hospital. The longer he has been known, the more has he been valued and respected: for, gentlemen, highly as you all must and do value him for his great abilities as a practical surgeon, deeply as I am sure you are all impressed with a sense of his many virtues as a man, still greater is the admiration for his talents, still more profound the respect for his worth, in those who have watched his practice and had the benefit of his kindness and advice for a longer period than has been the lot of most of you. If, indeed, his words were few, his practical remarks were many and most rich in value—a rare harvest of truth, gathered in a most extensive field of practice, after years of industrious toil, by this most excellent of surgical husbandmen. His sayings were most truly aphorisms, for he circumscripted the subject on which he spoke without burdening it with vague or useless matter, or deteriorating from the value of his remarks by pomposity or conceit. (Cheers.) His conduct has ever been marked by justice, kindness, uprightness, and humanity, but also by decision for his delicate consideration of the feelings of his patients has never given rise to vacillation in their treatment; nor has his mild, unobtrusive, and amiable nature ever led him from an independent line of conduct, or from a manly and gentlemanly bearing—in fine, his reputation as a surgeon has never been sullied by his character as a man (great cheering); and I may most truly say that, "Take him all in all, we never shall look upon his like again." He has already lived a long life, respected, esteemed, and beloved; may Providence yet grant him many—many years of health and happiness; and when that sad time shall arrive at which his earthly career shall terminate, and we shall see him here no more, his memory shall yet remain, cherished with the warmest affection, in the hearts of all who knew him. (Long-continued cheering.)

Mr Taylor having seconded the resolution, and paid a high tribute of respect to the merits of Mr. Vincent, a number of resolutions necessary for the carrying the first into effect were proposed and seconded by the following gentlemen:—Messrs. McWhinnie and Yonge, Dr. F. Ferre, and Messrs. Lee, Coote, Moore, Malden, Crookes, Perry, Holden, and Rogers. A committee was appointed, and Dr. Baly and Mr. Henry were requested to act as joint-treasurers, and Mr. Ware and Mr. Crose as secretaries. A large sum of money was at once subscribed; and, a vote of thanks to the chairman having been carried unanimously, the meeting separated.

RHEUMATISM AND ORCHITIS.

[To the Editor of the Medical Times.]

H.M.S. Victory, Feb. 16.

SIR,—Observing in the last number of the *Medical Times* that, at a meeting of the Medical Society of King's College, a case of orchitis was mentioned, in connection with rheumatism, I beg to communicate the following particulars of a case, which led me to consider rheumatism as an occasional cause of inflamed testicle.

Mr. —, aged forty, gunner, R.N., has been subject to chronic rheumatism for several years, generally experiencing a return of it after getting wet. He now (Oct. 1, 1844) has rheumatic pains in his left arm and knee, without any appearance of redness, increased at night so soon as he gets warm in bed. There is also

swelling of left testis, it being nearly as large again as the right one; very painful, pain coming on in paroxysms and extending to the groin and back. There is no gonorrhoeal discharge, nor has he had any; neither has the part been hurt. Four scrotal veins were opened; warm fomentations kept constantly applied; an emetic of ipecac administered; confinement to bed and low diet.

6. No improvement, and, considering it may have a rheumatic origin, gave him pil. colch. 3ss ter die in water; to continue the fomentations.

10. It has been gradually diminishing in size since the administration of the colchicum; which has had the effect of purging him smartly. Repeat colchic. et foment.

15. Testicle nearly reduced to its natural size; no rheumatic pains. Strips of adhesive plaster to be applied, so as to surround testis.

16. Discharged to duty.

On the 25th of February, 1845, he was again put on the sick list for rheumatic pains in his left arm and knee, and a swelling of the left testicle. The same treatment was adopted, with the exception of the local depletion; and on the 4th of March, the swelling having entirely subsided, and the rheumatic pains having left him, he was able to resume his usual occupation.

I am, Sir,

Your obedient servant,

W. M. S. J. ANDERSON, Assist.-Surg. R.N.

Dr. Zimmermann gives the following as the results of his researches on the fibrine of the blood:—

1. The fibrine of venous blood, whether buffed or not, is always soluble in solution of nitre. The solution is effected more rapidly or slowly according to the quantity of the salt of water, and the elevation of temperature.

2. We were not sufficiently acquainted with the solubility of the fibrine of arterial blood; but it appears to be less soluble than that of venous blood. The fibrine of the blood of the ox and calf, whether arterial or venous, is insoluble; the fibrine both of the arterial and venous blood of the dog is very soluble. The arterial fibrine of the horse is more soluble than the venous; the fibrine of the human capillaries is perfectly soluble.

3. Heat assists and cold prevents the solution of coagulated fibrine.

4. The dissolved fibrine resembles albumen, for it is coagulable by ether.

5. Alcohol after a time renders fibrine insoluble, but ether leaves it as soluble as before.

6. The heat of boiling water renders it insoluble.

7. The fibrine of the small vessels behaves in the same manner as that of the veins.

8. The fibrine of exudation is as soluble as that of venous blood.

9. The fibrine obtained by agitating blood is difficultly soluble, the same is the case with the buff of blood.

10. Putrefaction favours the solubility of fibrine.

11. Dried fibrine is more difficultly soluble.

12. Pressed fibrine is less soluble than when in a soft state.

13. The fibrine of the upper layers of the buff coat is less soluble than that of the inferior layers.

GOSSIP OF THE WEEK.

WAR-OFFICE.—Assist.-Surgeon E. Macpherson, from the 53rd Foot, to be Assistant-Surgeon, vice Stewart, promoted in the 61st Foot.—53rd Foot.—Gordon Kenmore Hardie, M.D., to be Assistant-Surgeon, vice Macpherson, appointed to the 9th Light Dragoons.—61st Foot.—Assistant-Surgeon Archibald Stewart, from the 9th Light Dragoons, to be Surgeon, vice Smith, deceased.—78th Foot.—Staff-Surgeon of Second Class Patrick Nicholson, M.D., to be Surgeon, vice Staley, appointed

to the 6th Dragoons.—Hospital Staff.—Assistant-Surgeon Samuel Currie, M.D., from the 16th Light Dragoons, to be Staff-Surgeon of Second Class, vice Nicholson, appointed to the 75th Foot; Alfred Gosden, gentleman, to be Assistant-Surgeon to the Forces, vice Newton, promoted in the Ceylon Rifle Regiment; William Nettleton Boyce, gentleman, to be Assistant-Surgeon to the Forces, vice Tweddell, appointed to the Ceylon Rifle Regiment.

WAR-OFFICE, March 2.—14th Light Dragoons: Surgeon Archibald Stewart, from the 61st Foot, to be Surgeon, vice Smyth, appointed to the 87th Foot.—61st Foot: Assistant-Surgeon Patrick Gammie, from the 80th Foot, to be Surgeon, vice Stewart, appointed to the 14th Light Dragoons.—80th Foot: Henry Carr Lucas, gentleman, to be Assistant-Surgeon, vice Gammie, promoted in the 61st Foot.—87th Foot: Surgeon Robert Dunkin Smyth, from the 14th Light Dragoons, to be Surgeon, vice Richard Arthur Pearson, M.D., who retires upon half-pay.—Hospital Staff: James McNab, M.D., to be Assistant-Surgeon to the Forces, vice Simeon Henry Hardy, M.D., who retires on half-pay.

NAVY APPOINTMENTS.—Surgeons: Alexander Baxter, to Volage; Thomas Heron Keown, to the Royal Marine Detachment at Port Essington; Jason Lardner, to be Superintendent in charge of the Anne, convict-ship.—Assistant-Surgeons: Frederick Harvey, to Volage; John Gunn, continued to the *Electra*; George Blinnie Hill (acting), to the *Ceylon*; David Omand West, continued to *Trafalgar*.

A singular case of affiliation was recently decided in the affirmative at the Salisbury petty sessions, the mother being a servant (Elizabeth Down) of the father (Charles Dew, Esq.). Mr. Lambert, solicitor, who appeared on behalf of the complainant, rested his corroborative evidence upon two facts—first, that the defendant had within a few days after complainant left his service, visited her, and taken tea with her, at a roadside public-house; and secondly, that the child had been born with five fingers and a thumb on its right hand, the defendant herself having been born with a similar malformation on both of his hands. He contended that the hereditary transmission of the additional finger was strong evidence of parentage, and in support of his view read several cases mentioned in Lawrence's lectures.—After evidence was given of these facts, Mr. Hoddling addressed the bench on behalf of the defendant, contending that the malformation of the hand was to be attributed to the mother's imagination (she constantly seeing Mr. Dew, and being bent upon affiliating the child upon him), and in support of this position cited several instances detailed in Walker "On Intermarriage," showing the effect of impressions made upon animals, in changing colour and modifying the breed.—The magistrates decided that Mr. Dew was the father, and awarded him to pay the full allowance for the support of the child, and its costs.

At a meeting of the Royal Society held recently, the following resolution was proposed:—"That it is the opinion of this special general meeting of the Royal Society of London for improving Natural Knowledge, that the award of the royal medal in Physiology for 1845 was made under circumstances characterized by great irregularity, and in violation of her Majesty Queen Victoria's regulations—viz., 'That the royal medals be given for such papers only as have been presented to the Royal Society, and inserted in their Transactions; and that therefore the said award ought to be considered as null and void.' The 'circumstances of great irregularity' having been explained to the satisfaction of the meeting, the following amendment was moved and carried with only three dissentient voices:—"That whereas the president of the society has already expressed, from the chair, an opinion on the irregularity which attended the award of the royal medal in 1845; and whereas the council issued new regulations with regard to the royal medals, as soon as they discovered that those

enacted in 1838 were inconsistent with the royal grant: it therefore does not seem expedient to the present meeting that any further proceedings should be taken in the matter." Thus ended the "storm in a puddle" elicited by the disappointment of Dr. Lee and the ambitious passions of one or two discontented supporters. It was the comedy of "Much Ado about Nothing" enacted gravely by F.F.R.S. ●

From Vienna we hear that the Austrian authorities have published a law which places homoeopathic practitioners under severe regulations. They must for the future purchase their drugs from the regular druggists—to register their names at the time of purchase, and to write down to what extent they afterwards authenticate the remedies so purchased.

A condemned prisoner in France has petitioned the authorities to be allowed to be under the influence of ether while being guillotined.

Mr. Paget has been elected assistant-surgeon to St. Bartholomew's Hospital.

Madame Hahnemann has been punished by fine in Paris for practising medicine illegally. She appears to have attended patients after the fashion of her late celebrated husband.

It is asserted, on hasty surmise, that etherization affects the cerebral system only—not touching the spinal or ganglionic. Recent experiments tend to throw suspicion on a supposed fact, from which Dr. Hale would draw support to his views.

The cholera has broken out along the shores of the Red Sea. The towns of Mecca, Medina, and Jeddah have, by all accounts, suffered very considerably from this scourge, and it is much apprehended that it will soon visit Egypt. There are various reports of the numbers of those who have been attacked by this disease; they are all great, but necessarily incorrect. The hajjis, or Mussulman pilgrims, seem to have suffered most. A sanitary cordon has been established at Suez.

QUARANTINE.—The Lords of her Majesty's Council have given the following orders:—1. Vessels from the Black Sea, with cargoes of enumerated or non-enumerated goods are to be released immediately from quarantine, even if they have touched at Constantinople, or any other port in Turkey from which clean bills of health are issued. 2. That vessels from Egypt and Syria are not included in the order alluded to; all vessels from Egypt and Syria to continue under the present regulations, viz., fifteen days with cargoes of enumerated goods (to be removed into a lazaret), and five days for vessels having cargoes of non-enumerated goods only, and having clean bills of health; and, in reply to the third query all vessels from ports in Turkey and islands under the dominion of Turkey are included in the order; and all vessels from ports in Egypt and Syria must, under present circumstances, be placed under the restraint of quarantine.

THE POISONING AND SUICIDE NEAR PRESTON.—The inquest was resumed on Monday evening upon the body of Fanny Leadbeater, aged nine years, who died from the effects of poison, supposed to have been administered by her mother to the deceased, and to four other children, on Friday evening last, the mother afterwards being found drowned. Thomas Moore, a surgeon, of Preston, said he knew the deceased, Mrs. Leadbeater, mother of the child who had been poisoned; he had known her ever since she was born. She was confined in an asylum about six years ago. He had seen her several times since, and considered her insane. When in a convalescent state on one occasion, walking in the neighbourhood of the asylum in the charge of keepers, she jumped off one of the bridges into the canal. When told she had drowned herself he was not surprised, and would not have been had she done so twelve months ago. The jury returned a verdict of "Insanity."

A letter from Frieswalden, Austria, of the 8th, states that the celebrated hydropathist Preisnitz has just received a stroke of apoplexy, and that his life was in great danger.

We notice amongst the obituaries of late several who have attained to very great ages. Recently Jane Culliford, of Yeovil, died aged

107 years. She was buried at Mudford, at her own request, and in the same grave which received her first husband's remains in 1785. Last week died Mr. Edward Dudley, of Dudley, aged eighty-five, leaving behind him the almost incredible number of 158 grand and great-grand children. On Saturday fortnight a large crowd collected at Kensal-green Cemetery to witness the interment of George Robinson, aged 103, one of the principal horse-dealers in this country: His son, eighty-three years, was among the mourners. But all these ages are much exceeded by that of an old woman now living in Moscow. She is now 168 years of age, and at the age of 122 she married for the fifth time!

We fear the march of intellect is tardy in some parts of England. A young woman at Bradford, troubled with epileptic fits, has, we are told, swallowed, on the prescription of a quack, a human skull powdered, and mixed with treacle, in occasional doses, as a remedy!

A fossil skeleton of an elephant has just been discovered in quarries near Macon, France.

Having on many occasions raised our voice against the disgusting system of intramural interment, we are glad to see that the Oxford city council have decided to petition Parliament for an act to enable corporate bodies in cities and boroughs to establish general cemeteries.

Mr. Ormsby Gore has given notice of his intention, in the course of a few days, to bring before Parliament the subject of Smithfield market, to move for leave to introduce a bill for its abolition, and to remove the market to some more appropriate site, comprising an area of not less than twelve acres, also to establish abattoirs or slaughter-houses in the vicinity of London. The average number of animals brought to Smithfield market is pretty well known, and it is stated that there are here sold annually 156,000 bullocks or other cattle, 21,000 calves, 1,500,000 sheep, and 29,000 pigs—the value of the whole being calculated at £8,250,000. Including the butcher meat, both fresh and salted, otherwise introduced into the metropolis, the total value yearly is presumed to be from ten to twelve millions of pounds sterling! The yearly revenue which the Corporation are understood to derive from a small toll on cattle brought to market is nearly £4,000. The Common Council, a few months since, voted the sum of £20,000 to be expended in enlarging the market.

Mr. Charles Hooton, formerly editor of the *Leeds Times*, and author of "Bibbery Thurland," "Colin Clink," &c., died last week at Nottingham from taking an overdose of morphia. He had been irregular in his habits, and was subject to ague and shivering fits caught during his residence in Texas and New Orleans.

The sugar countries, it has been satisfactorily proved, are enabled to supply us with 100,000 tons of sugar beyond the 260,000 tons which are our regular supply. A large cargo of sugar has recently arrived in London from Spain.

M. Soyer, of the Reform Club, has received instructions from the Government to proceed immediately to the Lord Lieutenant of Ireland, and to submit his plan of a model kitchen for the preparation of soup for the poor on a large scale, which, if approved of, will at once be carried into effect. Good soup unquestionably is (in its way) a very good thing; but if M. Soyer entertains the notion that a savoury wash of potherbs will altogether obviate the necessity of eating solid food he is egregiously wrong. The stomach is a most expert chemical analyst, possessed of very fine reasoning powers, and will soon find out the difference between nutritious meat gravy and M. Soyer's potherb juice:—yes! though he plies the pepper-box ever so strong, and uses a world of curry powder. *A propos* of soup, the Total Abstinence Society of Liverpool lately adopted a new plan of obtaining an audience for their lectures, having offered soup tickets to those who should attend. 483 of these tickets were distributed, and the attendance was goodly. We have not heard, but would lay a wager, that this soup was made of something better than potherbs.

The King of Prussia has nominated Sir D Brewster to be a Chevalier of the Order of Merit, in the room of Admiral Krusenstern, the celebrated navigator; and the King of Denmark has conferred the honour of Knight Commander of the Royal Danish Order of Dannebrog on Sir R. I. Murchison, in acknowledgment of his geological services in the north of Europe.

OBITUARY.—At Wellington, Somerset, on the 15th inst., Albert Langley, Esq., Surgeon, aged 36. Jan. 31, aged 78, Lynch Conway Gent, Esq., Surgeon, Penny Stratford, Bucks, in which town he had practised upwards of fifty years. Late, M. Ranque, M.D., Chief Physician to the Hospital and Prisons, and Dean of the Faculty of Medicine, of Orleans. Late, at Plymouth, aged 90, James Watt, Esq., Senior Surgeon of the Navy; Mr. Watt served as Assistant-Surgeon and Surgeon on board the *Ramilles* and other ships, in several naval engagements, under Keppel, Rodney, Saumarez, and Sir Richard Strachan. At 14, Heriotrow, Edinburgh, on the 20th inst., John Pitcairn, M.D.

ROYAL COLLEGE OF CHEMISTRY.

On Friday week his Royal Highness Prince Albert, attended by Major-General Bowater and suite, honoured the laboratory of the Royal College of Chemistry with his presence. His Royal Highness, as our readers are probably aware, passed his collegiate life at Bonn, an university long celebrated for the learning of its professors, and the assiduity of its students. From Bonn, too, came Dr. Hoffmann, the professor of chemistry at the college.

During the visit of his Royal Highness to the institution in Hanover-square, he witnessed, with much apparent gratification, some experiments on the combustibility of metals when exposed to the action of voltaic electricity, developed from Bunsen's charcoal battery. His Royal Highness, after expressing gratification at the good order in which he found the laboratory appointments, questioned the professor, with the true animus of a practical chemist, as to many new discoveries in the science.

MORTALITY TABLE.

For the Week ending Saturday, Feb. 27, 1847.

Cause of Death.	Total.	Average of 5 Winters.
ALL CAUSES.....	1044	1068
SPECIFIED CAUSES...	1040	1061
Zymotic (or Epidemic, Endemic, and Contagious) Diseases.....	152	183
SPORADIC DISEASES.

LECTURES ON SELECT POINTS OF SURGERY.

By WILLIAM FERGUSON, Esq., F.R.S.E.

Professor of Surgery in King's College, London; Surgeon to King's College Hospital, &c.

ON CLEFT PALATE, AND ON STAPHYLOPLASTY.

Author's experience increased since the reading of his paper on these subjects in 1844, before the Medical and Chirurgical Society of London; nature of cleft palate; different forms and kinds of, its complication with harelip, effects of malformation on deglutition and on voice and speech; method of obviating defects by a modern operation of staphyloplasty, advantages and disadvantages of latter proceeding, indifferent success of the operation, although performed by most of the leading surgeons in Europe and America, success of Roux, Mitter, and Dr. J. M. Warren, apathy of British surgeons on the subject; author's investigations, anatomy and physiology of cleft palate first described by him; new operation proposed and performed by author, and its success in various instances; reviews of different proposals, by Roux, Bushe, Diefenbach, Pancoast, Liston, Mitter, and J. M. Warren; fit cases for operation, age proper for its performance; author's operation described; ligatures and knots, new knot, after treatment; causes of failure of operation; examples of success of author's plan; effects of operation on voice and speech, &c.

(Continued from p. 26.)

Surgeons have long been familiar with the difficulty of keeping the parts quiet during, but especially after, an operation, and many ingenious proposals have been made to obviate this. The most simple and, perhaps, most reasonable was the plan of after-treatment pursued by Roux. The patient was enjoined to silence, and to abstain from any effort at deglutition; he was not permitted to swallow his saliva even. But this did not appear sufficient in all cases, and the distinguished author of the operation proposed to separate the soft palate from the hard by a transverse incision, and the plan was afterwards recommended by Mr. Bushe, of New York (a). This method was advised in examples where the gap was large and involved the hard palate, and it would certainly permit the anterior parts of the soft palate to be more readily brought into contact. Diefenbach and Pancoast (b) have split the flap in the way

represented in this diagram (fig. 1). The latter

two halves of the velum to come together in the middle line, as well as to divide the insertion of the palate muscles, so as to prevent them straining the outward edges of the palate asunder." Mr. Liston (a) has advised that, "before the ligatures are finally secured, the parts being put on the stretch, an incision should be made on each side towards the alveolar ridge, through the anterior surface of the velum, by which method the edges come together more easily, and the strain is taken off the threads, so that there is less risk of their making their way out by ulceration." The accompanying diagram

Fig. 2.

palate on each side of the fissure, at the time of doing the operation. Both of these methods may be understood from this diagram (fig. 3).

Fig. 3.

Dr. J. M. Warren has stated (a) that he had found the following course to be invariably followed by success: "The soft parts being forcibly stretched, a pair of long powerful French scissors, curved on the flat side, are carried behind the anterior pillar of the palate; its attachments to the tonsil and to the posterior pillar are now to be carefully cut away, on which the anterior soft parts will at once be found to expand, and an ample flap be provided for all desirable purposes."

From the variety of plans here alluded to, it will be observed, that the difficulty of bringing the edges of the gap together, of preventing dragging on the stitches, or subsequent separation of the newly-united parts, had not been overlooked. It is singular enough, however, that none of them have had reference to the correct anatomy of the parts; indeed, scarcely an allusion has been made to this subject. Dr. Pancoast is perhaps the only party who has alluded in apparently precise terms to the muscles of the parts, for his incisions are intended, to use his own language, "to divide the insertion of the palate muscles." It so happens, however, that no palate muscle is inserted exactly in this direction. The line marked out (fig. 1.) runs parallel with the fibres of the palato-pharyngeus; and were the levator palati divided in the incision, it would only be by chance; indeed, it would be next to impossible to divide it in such a way; the knife would, in all probability, pass through the palate either on the inside or outside of the lower end of the muscle. In the quotation already given from Mr. Liston's work no allusion is made to the anatomy of the parts, and it does not appear that more was intended than to permit that relaxation which a gap on each side might be supposed to produce as regards approximation in the

mesial line. In the last edition of the excellent volume alluded to, which has come out since the appearance of my paper on cleft palate, and after the author inspected my dissection, it is advised that the incision "through the anterior surface of the velum" should be made "well down by the sides of the uvula." (fig. 2.) It is stated, too, after allusion is made to my proposal, that "if the fleshy belly of the circumflexus palati could safely be reached and cut, this would, so far as I can understand, put the parts in a still more favourable condition to come together. Its tendon is certainly divided by the incision above directed, properly and effectually carried out." Doubtless it had escaped Mr. Liston's memory that my preparation proves that the circumflexus muscle has scarcely any influence on the palate—a circumstance which I have alluded to in my paper. The "fleshy belly" of this muscle may be reached with nearly as much safety and facility as that of the levator, but it seemed to me that so little good would result from its division, that I was content with the statement as to its comparatively unimportant action. An incision "through the anterior surface of the velum" would not include any portion of the circumflexus, and one "well down by the sides of the uvula" could not possibly reach the tendon of that muscle. Mr. Liston(a) justly observes that "the union is apt to fail under any circumstances," and, moreover, adds, in reference to my own views, "and I think that this was found to take place in the hands of the above-named professor, even after the division of the muscles as he has recommended"—a thought the accuracy of which I cannot impugn, although the reflections on this subject do not seem to me to have been either so extensive or founded on such accurate data as one might have expected, in an authority so unquestionable and so impartial: for it does not appear that Mr. Liston had remembered the two successful cases which were detailed in my paper presented to the Medico-Chirurgical Society, nor the statement(b) which I had subsequently placed in his hands, that I had been successful with the practice in six instances out of eight wherein I had performed the operation in the manner alluded to.

In Mettauer's plans (fig. 3) no allusion is made to the anatomy of the parts; some of the little wounds through the palate must implicate a few fibres of the palato-pharyngeus, but the long incision on the lower surface of the palate cannot touch any muscular fibres. In Dr. J. M. Warren's incision with the scissors, a portion of the palato-pharyngeus might possibly have been divided; but this plan, like all the others above alluded to, while intended to produce mechanical relaxation, had no special reference to the anatomy or physiology of the parts.

There are cases of cleft palate with which it would be unreasonable to meddle: the gap being so large and the soft tissues so narrow, that union could not possibly be anticipated. It has been supposed that when the two portions of the uvula are observed to touch each other during deglutition, the operation may invariably be undertaken; but the fact is, that in almost all instances these two parts touch at this particular time, however large the fissure may be, and it is better to be guided in deciding upon the propriety of an operation by the condition of the parts otherwise. In most cases where the osseous palate is open, there will be less certainty of a favourable result than if the soft velum alone were implicated. If it seems that only a small portion of the fissure in the soft parts can be closed, it will perhaps be best to leave the parts alone, and to trust for improvement entirely to an obturator or false palate, for it has sometimes been found that when there has been union only to a small extent, the condition has interfered with the proper adaptation of the apparatus.

(a) "Operative Surgery," 4th ed., p. 572.

(b) "System of Practical Surgery," 2nd ed., p. 632.

The operation should seldom be undertaken until the patient has reached puberty. Much steadiness and self-command is required on his part, both during the operation and afterwards; and it is hardly to be expected that one under this age will have the fortitude to do what the surgeon expects of him. I have, in one instance, seen a youth of eleven years of age comport himself admirably during the operation; but any time between sixteen and four-and-twenty is that which should be preferred.

The mode of proceeding which I generally follow may be thus described:—The patient should be seated on a firm chair with his face to the light; the surgeon should stand a little in front, on the right side, and occasionally behind the patient. In this latter position he may see into the mouth by leaning over the face, and use his fingers with more satisfaction and facility than if he were always in front, for here he is apt to obstruct the light, and possibly fatigue his hands by holding them so long in an elevated position towards the roof of the mouth. With a knife such as that which I here show you (fig. 4) I make an incision, about half an inch

Fig. 4.

middle part of each margin should be seized with hookbeaked forceps (fig. 5), and transfixed (fig. 5.)

in length, a little above the free margin on each side of the cleft, whereby the levator palati muscle is divided. The knife is sharp at the point, and also at each side, so that it may be readily passed through the mucous membrane and carried backward and forwards to enlarge the wound to the requisite extent. The point of the blade is entered above the middle part of each soft flap, where there is the greatest thickness of tissues, and, whilst it is carried deep against the levator muscle, it is moved as just directed, and not withdrawn until the power of elevating the part seems to be done away with. If, when the knife is withdrawn, there should still appear strong muscular action in an upward direction, as may be ascertained by irritating the parts, it may be used again, as possibly the whole of the muscle may not have been cut across. All this can be best done while standing at the patient's side. The edges of the fissure should now be pared; the mucous membrane on the

with a narrow, sharp-pointed blade (fig. 6),

(Fig. 7.)

ing it in the course through which it has already passed, the thread intended to form the stitch will thus be brought through the opposite side of the palate, when one end of it (for it has as yet been double) can be drawn out so as to leave both ready for knotting. Two, three, or four more threads, as may seem requisite, can be introduced in a similar manner; and now all that remains to be done is to draw the edges together and fasten the thread. The foremost thread should be first tied in accordance with the ordinary mode of making the interrupted suture; and the others should then be treated in the same order in which they have been introduced. Should an additional suture seem requisite in any part of the fissure, it may now be introduced by pushing the same needle from one side to the other—for now, when the parts are more fixed by the sutures, this may readily be accomplished. Before fastening the two knots furthest back, the pared edges should be brought together to ascertain the influence of the palato-pharyngeus in dragging them asunder. If this action seems strong, or if there be difficulty in drawing the parts together, the threads should be pulled forwards, whereby the posterior pillars of the fauces will be put upon the stretch, when each should be cut about half an inch behind the uvula, in an outward direction, to the extent of a quarter of an inch, and then there will be greater relaxation. Long curved scissors, with

(Fig. 8.)

blunt points, like these (fig. 8), are such as I use for this part of the operation, and the same are good for cutting off the ends of the ligatures, which is the last step in the operation.

In some instances it may appear best to effect the division of the palato-pharyngeus before passing the stitches. If this be desired, the fibres can be put on the stretch by drawing the uvula forwards with the beaked forceps. It will rarely seem requisite to meddle with the palato-glossus, but if its division is thought advisable, the scissors just described will be the best instrument to use. A small horizontal wound in front of the tonsil, and about midway between the tongue and palate, as represented in fig. 9 (c), will suffice.

The hookbeaked forceps, and also those for seizing the threads, should be a little longer than those in common use; and the curved needle is similar to that often employed for the strangulation of hemorrhoids, navis, and such like growths.

This figure (fig. 9) will probably, in some de-

Fig. 9.

gree, elucidate the above description. It gives a view of the posterior nares, with a cleft implicating the whole of the soft palate, and a small portion of the hard. On the left side the mucous membrane has been dissected from the muscles. *a.* The levator palati, on which is marked the line where it should be cut across. *b.* The inner bundle of fibres of the palato-pharyngeus, which forms the posterior pillar of the fauces, with the black line indicating where the scissors should be applied. *c.* The palato-glossus, with the mark for division, if that should seem necessary. The tonsil lies between these two muscles. *ee.* The posterior extremity of the inferior turbinated bone. *f.* The septum. *gg.* The uvula on each side stretched apart.

I have named a stout silk ligature, as I think it preferable to any other kind. Sometimes I have used a hempen thread, but it is difficult to get the material sufficiently small and strong at the same time. I have never used the lead ligature, as recommended by Dieffenbach and others, and, from my experience of the operation, should not feel inclined to try it. The threads to be used should be well rubbed with wax, and it is highly advantageous to have them of different colours, whereby they can be more readily recognised during the proceedings.

In the ordinary operation, it has been found, on attempting to cast the common knot for the interrupted suture, that the first turn of the thread is apt to slip ere the second can be drawn. To prevent this, the points of the common forceps have been closed upon the first until the other has been brought upon it; or the surgeon's knot has been used (*a*) in expectation that, the first twist of it being double, there should be less risk of slipping. Instead of a knot, Sir Philip Crampton (*b*) has passed the two ends of the thread through an aperture in a bead of soft metal, which he has squeezed close upon them at the proper distance. Mr. Brooke has, with an ingenious method, by means of glass beads, proposed to improve the style of suture here. The common knot and the surgeon's I have used most frequently, for I have always supposed that the beads might increase the after irritation. Besides, I feel satisfied that, in the operation which I perform, there is far less dragging on the threads than under ordinary circumstances, and that there is consequently less tendency to slip. But the slightest elasticity in the lateral flaps, unless indeed they be very broad, will be apt to produce a slip; and, to obviate this, I imagine that a knot of this kind will be found very serviceable. On one portion of the thread I cast a loose loop, with a single turn; the other end being then passed through it, the loop is drawn tight, and the fingers are then pushed towards the roof of the mouth and margins of the fissure, as with an ordinary knot. If the loop is drawn tight there is no risk of slipping; it should hold, in fact, as if a metal bead were squeezed somewhat tightly upon the end within it. When suffi-

cient tightness is secured, as regards the wound, a knot should be cast on the two ends of the thread, as in the common mode of fastening an interrupted suture. This diagram (fig. 10) will

Fig. 10.

best explain the verbal description just given. Professor Pancoast has advised that the knots should not be left in the incision line, where they would be exactly over the wound, but that they should rather be kept to a side, as represented in one of the preceding diagrams (fig. 1). It will be found easier to do this with the knot I have just recommended than with the common one, or more especially the surgeon's; and, as I believe it is rather an advantage to keep them off the wound (for the ends are apt to lodge in it, thereby preventing union to a certain extent, and causing irritation on the raw surfaces), I advise you to think of this plan, which seems to me to embody the advantages of the beads, while the knots will, from their size, be less annoying to the patient than the materials alluded to.

When the operation for cleft palate is performed in the ordinary manner there is generally so much muscular spasm as to cause great difficulty in paring the edges, introducing the needles, as well as bringing and holding the cut edges together. By the plans recommended by me these difficulties are entirely done away with, or greatly modified. The first incision is intended to take off the influence of the levator palati: if it be successful the palate seems to drop a little, and it is not so forcibly dragged upwards and outwards as under ordinary circumstances. Some movement of this kind may possibly still be present, and it may depend upon some of the fibres of the muscle having escaped the knife. The palato-pharyngeus, being still entire, will draw the margins of the fissure outwards; but when this muscle is divided there will then be no longer any action of the kind. This muscle, however, has so little influence compared with the levator that it seems to me advisable not to divide it on all occasions until the probable amount of dragging upon the stitches has been ascertained. Even when its fibres are cut there will be some convulsive movement in the lateral flaps, for the part between the section and the attachment in front will be in some degree under the influence of muscular contraction; a shortening may take place when the parts are irritated, and this movement will be aided by the *azygos uvulae*, which throughout the whole proceeding remains untouched unless when paring the edges or passing the stitches. Whatever irritability there may be, however great the spasm, there will certainly be less difficulty in passing the needles, and less opposition to the closure of the fissure, than under ordinary circumstances. After the sutures are fastened, the parts are more quiescent than with the muscles entire; indeed, in the course of a few hours (if not immediately after the operation), the roof of the mouth may be touched or tickled as you choose, and there will scarcely be any movement observed. There is one advantage in the incision which I make on the upper surface of the flaps, which is probably not the least that I claim for my own mode of operating. The wound is in the course of a few hours filled with lymph, which so thickens and stiffens the palate that any twitching of muscular fibres that may have been observable before are no longer apparent.

However efficiently the incisions which I re-

commend may be executed, the operation may, nevertheless, fail. The ordinary operation for harelip, when performed even under the most favourable circumstances, will sometimes fail, and occasionally a simple incised wound in the skin will not unite. Such results are still more likely to happen in the operation for cleft palate. The causes of failure may be as obscure as they often are in other wounds, but sometimes we may see reason why it has not taken place, and it may be well to refer to some of the circumstances likely to lead to an unfavourable issue. The grand immediate object of the operation is to obtain union by the first intention, and this may be thwarted in various ways by the surgeon himself.

Hitherto, the principal cause of failure has probably been the dragging on the stitches from the action of the muscles, and the consequent disposition for the parts to be drawn asunder; and this cause, I would fain hope, may now be in a great measure obviated by the proceedings which I recommend. There may be a deficiency of adhesive action, or there may be an excess of inflammation. In one case the gap may fly open almost as soon as the stitches are removed, in another the process of ulceration may produce the like effect after the lapse of days. Sloughing may actually occur, and there may be defects in the performance of the operation to account for this as well as otherwise to cause failure. I believe that extensive incisions, whether on the plans recommended by Roux, Dieffenbach, Mettauer, Liston, Warren, or myself, may possibly induce defective circulation or excess of inflammation, and from either of these conditions sloughing is likely to happen. The stitches may be so numerous as to do harm, especially if drawn so tight as to impede circulation, or possibly there may be so few that the surfaces are not properly held together. The needles may be introduced too far from the margins, or not far enough, or perhaps the margins themselves may not be sufficiently pared. I imagine, too, that evil may arise from awkwardness in effecting the whole proceedings: for, if there be much manipulation, much squeezing, pinching, or poking with knives, needles, and fingers, the chances of adhesion are thereby diminished.

After the operation is finished, every care must be taken that nothing be allowed to interfere with the process of union. It is very certain that, if the patient were permitted to use the parts in the ordinary way, such as in eating, drinking, or even swallowing the saliva, they would be greatly disturbed, and adhesion might not occur. If all the muscles of the palate be left entire, as is the case in Roux's operation, the least effort at deglutition will cause considerable spasm and dragging on the stitches, and in examples where the gap is large it is easy to perceive that much harm might result on such an occasion. Even in the proceeding which I follow, perfect quietude cannot be obtained, for the tongue below, and the constrictors behind and above, will still, during the act of swallowing, have such influence upon the palate, as greatly to disturb the healing action. It is requisite, then, to restrain the patient from such evil chances until adhesion has become so firm that it cannot be readily severed. Roux used to prohibit the use of food for eight-and-forty hours or more, and to prevent the party swallowing even his saliva. But danger may arise from too strict an adherence to this practice: patients have been known to take food at all risks, and so break up the adhesions; others have become temporarily deranged; and the sudden deprivation from food has caused considerable shock to the system in many instances. Sir Philip Crampton (*a*) has not acted rigidly upon this rule, and has permitted some of his patients "boiled bread and milk, custards, soups, and jelly, twice or three times a day." In most of my cases I have given the patient gruel, soup, and wine frequently during the day,

(*a*) "Dublin Journal of Medical Science," July 1, 1843, vol. xxii.

(*a*) Professor Smith and Dr. J. Mason Warren.
(*b*) "Dublin Journal of Medical Science," July 1, 1843.

and have invariably noticed that those thus treated have recovered more rapidly than the others who have been refused all food and drink. The custom of permitting a hearty meal one hour before the operation should not be neglected; but there is great chance of its being ejected from the stomach during the proceedings, for there are few patients who do not get squeamish during the doings with the palate. Indeed, I have remarked the chances to be greater in those who have partaken most largely of food beforehand.

A tickling cough almost invariably comes on a few hours after the operation, especially if the uvula swells much, as it often does, so that it actually drops on the roof of the tongue and epiglottis, and I have found a draught containing sixty minims of the compound tincture of camphor, at bedtime, to be of great service in such cases. The bowels are usually constipated for the first two or three days, and I generally add a drop of croton oil to such a draught, with good effect. The patient may keep in bed, or sit up during the day, as he may incline; and, as a matter of course, when he is swallowing what you permit, he ought to do so with caution. On the second or third day after the operation, one, two, or more of the stitches should be removed; on the third or fourth day, if they have not already all been taken away, this should be done; they are more likely to do harm than good, if permitted to remain beyond this time. But the surgeon must use his discretion on this point, as indeed is necessary as regards all the after treatment, for I do not think it reasonable to give out rules which shall answer all cases. The mucus which accumulates about the roof of the mouth, particularly in those cases where there is an aperture left in the hard palate, must be taken carefully away, once or twice a day, with forceps, and it answers well to dry the parts with a bit of soft sponge, which has been previously wrung out of a weak solution of nitric acid. In the course of eight or ten days the patient is usually so far well that he may eat and drink what he pleases, in moderation, and also take exercise in the open air. In a few days more his recovery is complete.

Among the cases to which I have alluded in this lecture, several possessed peculiar interest, in so far as regards the views which I have now endeavoured to explain. One of the unsuccessful examples, according to Roux's plan, occurred to our esteemed friend, Mr. Bowman. I saw the operation performed; it was admirably executed, and everything as regarded the favourable condition of the parts justified a sanguine hope of success. Yet in eight-and-forty hours all the stitches had given way, and the gap was as open as ever. Some years afterwards Mr. Bowman repeated the operation, with the addition of the incisions recommended by me, and a few weeks afterwards I saw the patient with a palate as entire as if it had been so from birth. One of my own cases was still more remarkable. J. T. had been operated on by Mr. Tuson, of the Middlesex Hospital, three different times, according to the method of Roux, and the opening was left in all probability larger than it was at first. There had been a small point of union about the middle of the gap, which by the traction on the flaps had been stretched out into a narrow band, not thicker than a bit of twine. Mr. Tuson was polite enough to send this patient to me: I operated, and had the satisfaction of securing union throughout the greater portion of the soft palate. When it is considered that the edges of the fissure had been three times pared before I myself touched them, it must be admitted that the parts were in a far less satisfactory condition for an operation than at first.

Besides the instance above referred to, as occurring to Mr. Bowman, Mr. Partridge has had a successful one, and so has M. Simon; in both of these, however, some secondary proceedings were requisite. One of the most successful examples of my own proceeding occurred to Mr.

Storks. Union took place throughout, and in the course of a fortnight, it would have been difficult to discover what had been the state of the palate before, or what had been done by the surgeon.

Even under the most favourable circumstances, a portion of the gap may not unite, or may open again in the course of a day or two, and it is then requisite to repeat part of the operation; the edges must be pared afresh, and one or more stitches passed, as may be necessary. This should not be done till after the lapse of weeks or months. An opening left after the first operation, though of such a size as to permit the air to pass readily through it for ten or twenty days, may, after some little further time, so close as to cause little more annoyance.

In infancy, the principal evil from cleft palate is, that the food is apt to escape upwards into the nostrils, but as the child grows older he acquires such use of the parts that such an occurrence rarely happens. The voice now appears as the principal defect, and it is not difficult for one familiar with such cases to forecast the state of the part as soon as he hears the person speak. If there be lareph, or the cicatrix resulting from an operation, for this defect suspicion may be so much the stronger, but of course no one can say with accuracy, what is the state of the palate until it is thoroughly inspected. As the chief cause of annoyance is from the voice, the principal object of the operation is to effect a favourable change upon it. There has, perhaps, been less said or written on this subject than it demands. The surgeon has usually been content with giving an account of the condition of the palate after an operation, but it is as interesting to know something of the voice. On this subject a variety of statements have been made in accordance with the experience derived from isolated cases. Sometimes the effect seems almost beyond belief, so great is the improvement; but in other instances there is no perceptible amendment. This latter result often arises from an aperture in the hard palate, with which the surgeon may not have meddled, and, until it is closed with some sort of obturator, the air escapes so freely through it that the benefit from closing the gap in the soft parts cannot be appreciated to its full extent. Even in such a case, however, the tone of the voice will probably have been greatly altered for the better; and if the opening alluded to be filled up, it may sound almost natural. It would yet be foolish to imagine that speech should be perfect, for how could this be with a person who had never articulated distinctly at any period of life? Some have been so sanguine as to expect this, and have been greatly disappointed. The fact is, that the party, however successful the operation may have been, has still to learn both how to modulate the voice, and to articulate. Some make great progress, and in the course of a few weeks or months the result is such as to please the most fastidious. In others the changes are more slow, for a year or more may elapse before much improvement can be noticed; and there are some who from want of ear, of power, disposition, or perseverance, never make any satisfactory progress. In some of my own cases there has been all the improvement that could reasonably have been anticipated, but in others there has been very little. This I have attributed in some to the remaining imperfections in the palate, and in others to the want of care on the part of the patient to improve the pronunciation. I believe that all persons with this malformation have it in their power to speak more distinctly than they generally do. In one of the worst cases of cleft palate which I have ever seen, the party could articulate with considerable accuracy, and this was attributable to the care which she had bestowed in improving her voice. If, after an operation is successfully performed, the individual sets earnestly and methodically about modulating the voice and articulating distinctly, there seems nothing to prevent both being brought to a natural and average perfection. One of my patients was so zealous in his after studies that

he soon spoke with more distinctness and accuracy than is generally observed in persons in whom the palate has been originally well formed. I have known some, however, so stupid, obstinate, or careless, that they could not, or would not, pronounce the word "yes," excepting in the old way. A person with cleft palate seldom sounds the "s" at the end of the word, because the air in expiration passes mostly through the fissure and nostrils. Even after the operation, the air is likely to pass by the nostrils, unless the person be careful to open the lips properly. If he does this, and pushes the tongue forward with its tip against the lower front teeth, the "s" will then become distinct; and if this little lesson be readily undertaken and ably performed, there may be good hopes of speedy and great future improvement.

A COURSE OF LECTURES ON CLINICAL MEDICINE,

Delivered in the Theatre of Queen's College, Birmingham.
By SAMUEL WRIGHT, M.D.

Physician to Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham; Physician to the General Dispensary; Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

Sequelæ of the bowel complaint of 1816, as they appeared amongst adults, not observed in old people; comments upon the subject, illustrations: aetiology, why pathological actions are never strongly marked in old age; intestinal irritation a sequelæ of the bowel complaint; symptoms of it; pathological appearances, treatment, value of liquor potassa, hydrocarbonate of potash, observations upon, amenorrhoea cured by the bowel complaint, in other cases caused by it, gastro-intestinal flatulency, observations upon it; origin of the flatulency, treatment; alteration of the intestines, cause of, and comment; vital depression, case of, resulting from bowel complaint, particular features of it, treatment.

GENTLEMEN,.—Our last lecture treated of the sequelæ of the bowel complaint of 1816, as they appeared amongst children: the present one will continue the subject in its relations to adults.

In elderly or aged people, it was seldom that the consequences of cholera presented any features of pathological interest. When the disease was severe with them, they rapidly sunk before it, without exhibiting any signs or symptoms of rallying or reaction; when it was milder, and they recovered, there were left no traces of its visitation, beyond simple debility.

Ailments, pathologically the same, are apt to vary in their manifestations, according to the age, health, and strength, of their subjects. Inflammation, for instance, puts on one appearance in infancy, another in adult life, and another in old age; in these several seasons, also, do its tendencies and products vary. Pneumonia, in childhood, rarely extends to pleuritis; but it has the worse liability to implicate the tracheo-bronchial membrane in inflammation: this is the more dangerous, because lymph, coagulable or prone to organization, is the chief result of inflammatory action at this age—pus is a less common produce. In the adult, pneumonia, if not very circumscribed and deep-seated, rarely fails to involve the serous covering of the lung, and the product is generally both lymph and pus. In old age, pneumonia is a rare affection, and rarer still is pleuritis accompanying it. Bronchitis, with congestion of the pulmonary vessels, is the chief ailment of the respiratory organs at this season of life; and a profusion of mucus, with a thin watery pus deficient in globules, is almost the only secretion or exudation it affords.

The life of the body is not a separate immortal something, like *mind* or *soul*; we know nothing of it except through the organs which manifest it, nor can we conceive it to have, like *our eternal entity*, an existence apart from the organism which exhibits it. Bodily or physical

life is made up of the functions of the several organs that enter into the constitution of the living frame. Its manifestations, therefore, vary with the number and degree of structural perfection of these. Hence it is that its irregularities, which we call disorders, vary with the subjects of them. They have one aspect in childhood, because the organs are not fully developed and constituted; another in meridian life, because the organs have then reached their maximum strength and stability; and another in senility, when these organs have lost their vigour, and are preparing to pass back again into the elements from which they sprung. Pathological actions are nothing more than physiological ones out of order: their number, and variety, and degree, will, therefore, vary with the organs and the strength of their action. Thus it is that morbid functions, and the produce of them, are nothing so remarkable in advanced as in middle and earlier life. There is not in old age enough of the *vis vite* for the display of pathological phenomena. The powers are either prostrated at once by being perverted; or this perversion, if lasting, is not intense enough to invest itself with any marked character.

Hence you see why the bowel complaint I have spoken of had no particular *sequela* amongst old people. With adults, however, whose organic processes were not only capable of derangement, but capable also of exhibiting this immoderately, the converse happened.

Troublesome and continued intestinal irritation was a common *sequela*. It was not accompanied by purging, properly so called, but there was an inclination of the bowels to laxity, and to an immediate expulsion of their contents. This was particularly the case after the ingestion of diluents, whether warm or cold; the patients expressively observed, that they had no sooner swallowed any liquid, than it "ran through them like water." They ejected solid food less quickly, but even this was not long retained. There was a sense of soreness or smarting of the bowels, generally increased by sustained pressure: occasionally sharp pains, of variable situation, were complained of in the abdomen. There was more or less fever, a quick irritable pulse, and redness of the tongue at its edges and tip, with elevated papillae. The saliva was almost constantly acrid, often strongly so, and not unfrequently there was nausea or vomiting.

In these cases the muciparous glands of the intestines appeared to be chiefly affected. The symptoms were not strongly enough marked for subacute gastro-enteritis, nor did I see any *post-mortem* proof of this in the cases which I examined. The glands of Peyer and Brunner, as well as the solitary ones of the intestinal membrane, were considerably enlarged, and often vividly red; the blush, however, was confined to these particular structures. This morbid state was doubtless the result of the long-continued irritation from which the bowels had suffered. You sometimes remark similar appearances in people who have habituated themselves to purgatives, especially of the hydragogue kind.

The treatment which I found most effective, consisted in maintaining steady counter-irritation over the entire abdomen, by means of turpentine, or a warm liniment, and in exhibiting medicinals calculated to allay excitement and give tone to the bowels. A favourite mixture, the good effects of which you have often witnessed of late, composed of infusion of buchu, having in every half-pint a drachm each of *liquor potassae* and laudanum, and two of three drachms of tincture of henbane, did excellent service in the dose of an ounce three or four times a day. Alkalis are of great value in irritation of the intestines, and, if their glands be chiefly implicated, perhaps there is none preferable to liquid potash. It may sometimes be advantageously given without any other medicinal, and then its taste, which is often complained of, may be completely covered by administering it in milk.

After the subsidence of the more urgent

symptoms, I ventured to exchange the effusion of buchu for that of calumba, as being a more direct tonic; and gave additionally in the mixture, hydriodate of potash, commencing with one grain, and gradually increasing it to four grains, for a dose. This formula likewise answered very well; but the iodine salt rather increased the irritation of the bowels if exhibited at first. You will find that the preparations of iodine are much more available in chronic than in acute disorders of glandular apparatus. I have generally remarked that, in the latter states, they do more harm than good. They are inestimable remedies, but they are not things to be trifled with or given at random: according to the discretion with which they are exhibited, they will prove either useful or injurious. The hydriodate of potash is the best of them: it should be given in solution, and always in conjunction with an alkali. In some cases which did not completely recover under this plan of treatment, but in which there was evidence rather of debility than of irritation of the bowels—for there was no abdominal pain, no fever, no redness or elevation of papillae of the tongue, but a white fur upon it—the sesquichloride of iron produced admirable effects. In atonic conditions of mucous membranes, it is sometimes invaluable. You may give it in water, or in infusion of quassia: this is almost the only tonic vehicle with which the salts of iron do not strike a black colour.

There were a few cases in which the occurrence of the bowel complaint proved curative of amenorrhœa: the uterine function, in some of them, was restored before the subsidence of the purging; in others, after it. Here we must suppose the uterus to have become excited sympathetically with the irritated intestines, as we occasionally observe in giving cathartics to promote menstruation.

Sometimes the purging caused a troublesome leucorrhœa or a coloured vaginal discharge, acrid and offensive. I have known these to follow the use of strong purgative medicines in women of irritable, sanguineous temperament, and in others suffering from debility or cachexia.

As suspension of the catamenia, again, was more than once observed to be successive of the cholera of 1816. There is no accounting for these anomalies: what cures an ailment in one person will cause it in another. Diastolic purgatives are called emmenagogues, and yet the history of their action is not without proofs of the menstrual secretion having been arrested by them. Perhaps, however, in the instances wherein amenorrhœa occurred as a *sequela* of bowel complaint, it was not so much from the local irritation of this as from the debility it induced. Whatever directly or indirectly depresses the vital powers has a tendency to interfere with the menstrual function. It is thus that we so often see it suspended by moral emotions, such as sudden fright, fear, grief, anxiety, by insufluent or innutritious food, by over exertion, debilitating ailments, mercurialization, bleeding, &c. In some cases the excessive action of the bowels, especially when this was dysenteric, was attended or followed by hemorrhoids. This was an annoying as well as a painful *sequela* to such as suffered from its visitation for the first time. Dyspepsia, with distressing gastro-intestinal flatulence, was another and a very common consequence of the cholera. You sometimes observe this to be the result of certain debilitating causes. Sexual excesses will produce it; so will drunkenness: so will tobacco-smoking amongst subjects not fully initiated in that filthy habit. I have known it follow the abuse of mercury; it is often successive of large bleedings and of hemorrhages. I saw the other day, in consultation with Mr. Amphlett, a lady who has long suffered from flatulence of the most distressing kind; her bowels are sometimes so distended as to make the girth of her abdomen equal to that of a woman at the close of uterogestation. Beyond this trouble she has few symptoms, and those not marked, of dyspepsia. Her last confinement was attended by frightful

hemorrhage, from which she rallied with difficulty, and which left her in a state of extreme prostration that continued some months. In this state of debility, she became the subject of flatulent distention of the stomach and bowels; and, excepting occasional intermissions, it has continued ever since, and resisted all plans of treatment.

Some of the cases in which this flatulence was sequent of bowel complaint were very severe. Distressing feelings of suffocation, and often agonizing spasms, were produced by it. Its origin is not easily accounted for. The quantity was sometimes so profuse, and the accession so sudden, as almost to lead to the belief that it had actually been secreted. With the exception of the swimming-bladder of fishes, we know of no organ in its normal state secreting gaseous fluids: still, there is no saying what the products may be of organs in morbid states. To myself, there is nothing contrary to probability in the opinion expressed by some physiologists (Mareudie and Girardin), that gases may occasionally be the result of secretion; and we know that pathologists have cited some cases which do not appear to admit of any other explanation. I do not wish to aver it as my positive belief, that the intestinal gases, in the instances I allude to, were the produce of secretion; but in some of them any other mode of accounting for the anomaly was far from conclusive. As I have said, it not unfrequently happened that the distention occurred suddenly—in the space of a few minutes. Now, the only two likely sources of the gaseous fluid, other than secretion, would be the swallowing of atmospheric air, and the fermentation or decomposition of alimentary materials. To either of these, however, the sudden occurrence of the distention applies objectionably. There are some people who are very expert at air-swallowing; conjurers and ventriloquists practise it in certain of their arts. But to do it adroitly requires some experience, and even its adepts cannot fill their stomachs very quickly; certainly in nothing like the time that the distention often occurred, to my own knowledge, amongst the dyspeptics I speak of. Some people suffer from flatulence, clearly from the ingestion of atmospheric air; but they are generally conscious of swallowing it, and moreover, the gaseous accumulation in this manner is slow. Further, I was not able, in certain of the cases which I investigated, to discover any proof whatever of an having been swallowed; the proofs rather were against such a thing. One of the strongest of them was the fact that the distention commenced in the bowels, and extended to the stomach, instead of conversely, as happens when air is swallowed. This also is an objection against the gaseous fluids having been the produce of fermentation of food just eaten; and a further one is, that the distention was more common when the stomach was empty, than after a recent meal. Food, again, made little difference; meat, milk, and old bread, were the chief sustenance in some cases, and in others, vegetables were freely eaten, but the symptoms remained pretty similar.

The decomposition of feculent matter in the intestines might possibly have caused the evolution of the gases, but this is to be objected against in the following surmises:—1, there was usually so much action of the bowels as to render it improbable that much fecal matter could be detained in them; 2, the evolution of gas in ordinary decomposition is very slow compared with that in the instances I speak of; 3, the sudden occurrence, suspension, and recurrence of the evolution of gaseous matter are inconsistent with the continued presence of decomposable materials in the intestines, and the constancy of circumstances favourable to the process of decomposition; 4, there was nothing whatever to prove that, at the time the gaseous distention of the bowels occurred, there was more fecal accumulation in the intestines, or greater facilities for its decomposition, than under other, the opposite, circumstances.

Whatever the cause of the distention, the cure

of it was often somewhat difficult. As I told you, in a previous lecture, ammonia is an excellent remedy in flatulence of the stomach, and assafoetida equally so in flatulence of the intestines. Infusions of cuscutaria or cascarrilla, which are valuable carminative tonics, I was in the habit of employing, with from thirty to fifty grains of carbonate of ammonia, in eight ounces of either: of this mixture two table-spoonfuls were given every three or four hours, or less often, as the case required, with very good effect. When there was evidence of gastric or intestinal irritability, beyond what may be occasioned by the accumulated flatus, tincture of opium or of henbane formed a useful addition to the mixture. Five grains each, of compound rhubarb pill and assafoetida, were advantageously given at bedtime, when the bowels were torpid; and when in the reverse state, the aperient was well substituted by soap-and-opium pill, extract of henbane or of poppies. Occasional friction of the abdomen, or counter-irritation, generally contributed to assist the distended intestines to contract upon their troublesome contents.

In some cases this form of treatment was all that was necessary; in others, though the carminatives and stimulants sufficed to dissipate any flatulence, they did not prevent the renewal of it. In these latter, chalybeate tonics, quinine, and strychnine, were of more avail. (The tonic services of strychnine I have often shown you of late. I cannot now further speak of it than to promise a separate lecture upon it on a future occasion.) Generous living, with abstinence from the coarser vegetables, cold bathing, or sponging the body in cold salt water, and free exercise in the fresh air, constituted most serviceable auxiliary treatment.

I never met with a case of ulceration of the intestines during the attack of bowel complaint; and with only one which could be considered a *sequela* of it. The following are the condensed particulars:—

Fanny Whitehouse, aged thirty, was attended by Mr. Carter, of the Dispensary, for simple fever, from which she recovered. She was subsequently seized with bowel complaint, the consequence of cold, as she thought; this was relieved, and she became nearly convalescent; again, however, it returned, and was again arrested by remedies. She then remained free from all active symptoms, except occasional bearing-down pain, for several days, when, about two o'clock one afternoon, she was suddenly seized with intense pain in the bowels, accompanied by severe retching; these lasted unremittingly until six o'clock. Leeches were ordered to the abdomen, and opiates were administered, without abating the pain. The symptoms continued without change for a certain time, then ceased suddenly, and the patient began to sink. She died the next day. The peritoneum was injected, in some places intensely; the omentum was remarkably vascular, and its vessels very dark. The intestines, as first exposed, were covered with a blush of the brightest crimson I almost ever saw; in places they were more pale, and in others they were covered with fluid lymph; this floated occasionally amongst the convolutions of the intestines. About six inches beyond the ileo-cæcal valve, the bowel was found perforated on a spot of ulceration the size of a sixpence. This is the specimen which I exhibit to you. You see an areola of inflammatory hue; more centrally, a dark spot marking the destruction of the mucous tissue, and within this, where I direct the probe, an orifice. Hence issued the fluid contents of the intestines, which we found in the lower abdominal and pelvic cavity, to the extent of a pint. There is only one point of perforation, but there are several places, as I show you, where ulcerative absorption has occurred; in some of them only the mucous tissue is destroyed; in others, the muco-vascular tissue is gone, leaving only the peritoneal covering intact.

In this case there was nothing to induce suspicion of ulceration of the intestines; but the suddenness of the pain, and the absence of cer-

tain of the usual symptoms of peritoneal inflammation, led us to surmise the nature of the mischief, and left us the choice of only few remedies. The treatment was rather palliative than other, for we saw no justification of active measures; and this opinion was confirmed in the *post-mortem*.

Vital prostration, of variable degree, was another common *sequela* of the cholera of 1846. I met with several cases of it, but one in particular may be worth recording. Though the most severe of any I saw, its modifications may be taken as a type of the generality. It occurred in the person of a man named Armstrong, whom I treated in consultation with Mr. Heeley, of this town. On my first visit, early in the evening, I found him sitting in a chair, with his wife standing by his side; he held her by the apron, and most imploringly begged her not to leave him. His face was excessively pale, and quite cold, as was his head; pupil contracted to a point, eye glaring, and anxious looking; respiration hurried and irregular; frequent nausea; tongue pale, sodden, and covered with a thick white fur; hands and feet quite cold; pulse 146, and very feeble. The poor fellow was in a state of constant apprehension lest somebody should carry him off or kill him. I learnt that he had suffered from distressing bowel complaint for nearly a fortnight previously, and that it had left him in the state described. For several days he had partaken of no solid food; and for as many nights he had had no sleep. It seemed to me that he was the subject of the irritability of exhaustion; in this opinion Mr. Heeley concurred, and we forthwith gave him two drachms of *sal volatile* in half a teacupful of water. In a few minutes his pulse fell nearly twenty beats per minute, and became stronger; his pupil dilated slightly, and he said he felt warm. We then gave him other two drachms of *sal volatile*, which produced still further improvement. We then left him, ordering his feet to be put into hot mustard and water, and subsequently a mustard cataplasm to be applied to the epigastrium. He was to take a breakfast-cup of gruel for his supper, with a table-spoonful of brandy, and twenty drops of laudanum. On calling the next morning, we found him more free from ailment than he had been for several days past. We ordered him stimulating medicines, brandy and water occasionally, and nourishing diet: the former we were several times obliged to increase in potency, from the state of collapse into which he frequently fell. More than once he became so prostrate and foolish that I was afraid of his sinking into imbecility. Perseverance, first in stimulating and subsequently in tonic and nutritive treatment, effected his restoration.

The cholera of 1846 had no other *sequela*, that I know of, worthy of comment.

LECTURES ON THEORY AND PRACTICE OF MEDICINE.

By Dr. CORRIGAN.

Delivered at the Richmond Hospital School of Medicine, Dublin.

Lecture II.—INFLAMMATION.

(Continued from p. 3.)

At our former meeting, gentlemen, I drew your attention to the principles essentially necessary to the proper understanding of that compound phenomenon to which the term inflammation is given. I explained to you that under its most ordinary form it consists of lesions of three functions. Firstly, a lesion of the circulating function, or the carrying of the blood through the capillary vessels; secondly, a lesion of the nutritive function; and thirdly, a lesion of the function of innervation. I also showed that a definition of the compound lesion—inflammation, as applied to any one organ of the body, is inapplicable to any other, inasmuch as there are no two organs in which these three elementary functions are related to each other in the same proportion.

In cellular tissue, for instance, and in serous

membranes, which are but modifications of cellular tissues, the function of nutrition is the only function active in the healthy state; at least there is no perceptible trace of red vessels, and innervation is dull.

Then turn to the lung, and you find the greater portion of the function of the organ being occupied by circulation, and pass again to some other organs or parts which are endowed with exquisite sensibility, and you find innervation the most prominent function; hence arises the insurmountable difficulty of constructing a definition of inflammation. Did the whole body consist of a mass of cellular tissue, then the proportion which these functions bear to each other in any one portion of it would exist equally in any other portion, but, as in different tissues they are in different proportions to one another, there can, therefore, be no definition which will have a general application. Besides, another great difficulty attending such an attempt is, the fact that the relative proportion of these functional derangements in any organ attacked is not always necessarily the same.

You will now understand why the appearances denominated inflammation vary in one organ as compared with another, or in one individual as compared with another, owing, in some instances, to peculiarity of constitution; in others, to the peculiar character of the inflammation, technically called its type.

We now come to investigate this compound lesion, termed inflammation, and we shall devote our attention to the consideration of each lesion separately. Let us examine the capillaries of a part in a state of inflammation, as shown in the diagram before us; here let us understand what is strictly meant by the capillary system. It consists of a mesh-work of vessels carrying red blood, permitting the passage of the blood backwards or forwards, as the case may be, between the arteries on the one hand, and the veins on the other. If we observe what takes place on the application of a stimulant to these vessels, selecting for the experiment the web of a frog's foot, or, still better, the tail of a fish, we find the following features present themselves:—The arteries on its application at first diminish in size, and the circulation of the globules through the capillaries becomes excessively rapid; whether this rapidity is, strictly speaking, the consequence of the contraction, or the rapid motion of the globules the cause of contraction, is a theoretical point which we need not trouble ourselves with. Keeping the eye on the part, the circulation will be observed after a little time to become much slower, and the coloured globules which occupied the centre of the vessels are now seen to approach its sides, and gradually to become attached to them; they become more and more fixed, the vessels more and more dilated, the part becomes darker and darker, the circulation at length ceases altogether, and the part has now died. This is mortification in its simplest form, such as we see it in gangrenæ sculis, or after frost-bite, where the vessels have been killed. There is here no combination of lesions. But let us digress for a moment, and suppose there be added to the lesion of circulation a lesion of nutrition in the part giving rise to an effusion of the liquor sanguineus—the granules of lymph, together with some serous fluid from the capillaries, causing swelling of the tissue engaged—we then have what is called moist gangrene, that of most frequent occurrence.

Having thus followed the vessels through these phases up to their actual cessation of action, involving the death of the part, the question now suggests itself as regards the practical bearing of the subject before us, for it is in that sense only that we take up these matters; this question suggests itself:—What is the state of those vessels when the part affected is redder or darker than natural—that is, when the local lesion is in its second stage? We call that the first stage in which a stimulant is either locally applied which has made the vessels contract,

or in the case of an internal organ where a similar diseased action has taken place. This first stage lasts a very short time—so short as hardly to come under the notice of the physician at all. It is the second stage, when the part has become redder or darker than natural, that he has to deal with. Now, as to the state of the vessels in this stage: for upon our views on that subject does our treatment depend. Are they in a state of increased power, or in a state of debility? On the two sides of this question are ranged opponents; but, instead of putting the question in this way, let us put it thus:—What is the condition of the vessels as regards the contained quantity of blood? The quantity of the blood in the dilated vessels will be at once admitted to be greater than natural; but we are not hence to infer the existence of increased power in those vessels.

It is argued in favour of debility, that as the first effect of the application of a stimulant has been to diminish the calibre of the vessels—and as, upon a continuance of that stimulation, dilatation has followed, until at length the vessels have altogether lost their tone—the vessels in this second stage have given way in their fibres, or have yielded just as the muscular fibres of an intestine or bladder will at length yield, after repeated contractile efforts. Some curious microscopical observations have been made upon the fibres of the capillary vessels, which seem to show an exceedingly strong resemblance in their fibres to the involuntarily muscular fibres of the intestines; and this, the advocates on the side of debility say, tends to show that the fibres of the capillaries are subject to the same changes as the muscular fibres of the intestine. For instance, in the disease called ileus, the intestine, after being distended for some time, loses the power of contracting, and death occurs as the consequence of this loss of power, without any inflammatory action whatever. Let us here digress for a moment, and turn our attention to a fact connected with the point we are discussing. Suppose we admit this to be the structure of the capillary fibres, the argument is by no means to be extended to the larger arteries which supply them with blood; it does not follow that these latter vessels are supplied with muscular fibres. The effect of a stimulant on the capillary vessels shows, I think, how entirely independent they are of the heart and larger arteries. To argue that the larger arterial tubes are muscular, because the capillaries are so, would be, I think, as erroneous as to infer that the tendon of a muscle, because continuous with the muscle, is contractile also.

The proper view to take of the heart, in reference to diseases, is to look upon it as a pump for the supply of the blood, and the larger arteries as so many supply tubes merely carrying this fluid to the capillaries, which are the more active agents in health and disease. Comparative anatomy tells us that the capillaries exist before the heart and arteries, and that these latter are not essential to the changes that occur in the capillaries, which are of themselves adequate to carry on the circulation. You have only to take a small sprat or minnow, or any of the smaller fish, and cut out the heart and arteries, or cut the animals across, and still you will find the capillary circulation going on, proving their function to be independent of the heart and larger vessels.

In support of the doctrine of debility there are also adduced the results of treatment. Where distention of the vessels has persisted for a long time, as in chronic ophthalmia for example, the best effects are derived from stimulants to enable those vessels to contract; and the same treatment is equally applicable to internal organs. Where scrofula or general debility exists, the effects of tonics and good air are not less marked. But on the side of the vessels being in a state of increased power, it is said depletion is often more necessary than stimulation. But here again is another error in reasoning. Because relief was afforded by depletion—*ergo*, the action was one of increased power.

Suppose we have to deal with a distended capillary, or capillaries, and remove a portion of the contained blood, does it follow that the state of distention was, therefore, one of increased power? As well might it be said of the distended bladder from which we have drawn off a quantity of its contained fluid that the organ, in its greatly increased state of distention, possessed a proportionate increase of power. In the same way, if we take the other side and use the same argument, we can obtain conclusions exactly opposite; we might say we draw off a quantity of blood, and thus enable the vessels to contract and acquire this lost power; therefore we might argue their previous state must have been one of debility, as in the case of the bladder that was relieved of its superabundant fluid, and thus restore its power.

Another argument adduced in favour of increased power is the fact of the blood flowing from an inflamed part in increased quantity. But in favour of debility we might say, the capillaries of the parts are distended with an unusual quantity of blood, from their debility permitting dilatation. If there were increased capillary power the vessels would contract and diminish their contents; thus, you see quite a contrary inference may be drawn from the same premises. Another argument in favour of increased power, which the student may see in the books that every day come before him, is increased growth—namely, that inflammation and increased growth are analogous actions; that, for instance, we see hypertrophy or increased nutrition of an organ occur as the consequence of inflammation, and there is cited the circumstance of the growth of the stag's horns. This increased growth, or nutrition, describe it as we may, is, they say, increased power; and hence, accompanying inflammation, there must be increased power. Here is another mistake in reasoning: they forget that nutrition and circulation are totally independent functions, and that the former can exist where no trace of a vessel can be detected. Again, let us even admit that the increased circulation in the stag's growing horn is analogous to inflammation—*ergo*, is it to be inferred that that inflammatory action is one of increased power in the organs? The granules of the fibrine or nucleated cells are thrown out by the vessels to form the horn or new growth; and if it be even admitted that this function is one of increased power, yet it by no means follows that the capillaries carrying these nucleated cells are in a condition of increased power.

Let us turn to pathology for an explanation, and take, for instance, an exceedingly common disease, the large fibrous yellow liver, as it is called, occurring in subjects weakened by various debilitating causes; here the liver has been for a number of years subjected to a mechanical obstruction of its circulation. Its capillaries have been in a state of distention from vital or mechanical debility, while its bulk has been increased by excess of nutrition. Thus, then, whether the capillaries be distended by mechanical causes or by debility, the function of nutrition deposits the fibrous granules or nucleated cells constituting the hypertrophy of the organ, which may attain a bulk three or four times its natural size. To admit that when the nutritive function is in excess, the capillaries of the part are, therefore, in a state of increased power, is extending an inference further than we are entitled to do in correct reasoning. Let us take the growth of the foetus in the enlarged uterus; here there is throughout the vagina distention of the vessels, principally corresponding to the situation of the placenta; the vessels are larger, but they are also thinner, than usual, and do not possess the strength of the common arteries elsewhere, and the blood moves slower than under ordinary circumstances. It matters not, for the supply of the function of increased nutrition, how the nucleated cells or granules of fibrine are carried, whether the capillaries carrying them are dilated from strength or debility, the two functions are so far independent of each other that no argument can be drawn

from one as to the state of the other. I can point out to you instances where, with general signs of positive debility, the nutritive function was yet extremely active—for example, in animals badly fed, subjected to the influences of bad air and cold to the surface of the body. You see an exuberant growth of hair, such as you might only expect to find in the full vigour of the animal, while, on the other hand, with everything that indicates a superabundance of red and highly oxygenized blood, the function of nutrition seems in many cases comparatively diminished. What conclusion, then, are we to come to? Do not join one sect or another; in medicine never attach yourself to any particular dogma, for it may be said that hardly a single view can be made generally applicable, on account of the changes and the variety of phases that may occur in the several diseases that come before you.

One day a case may present itself, with the evidences of increased power, requiring blood-letting, tartar emetic, everything, in fact, to lower the system; while the very next may be a case in which the capillaries are in a state of extreme debility, and thus you might be led into making the gravest mistakes. In the latter condition, time and stimulants must be had recourse to, with the avoidance of everything that might tend to lower the constitution.

There is the first condition of the capillaries—contraction, which, as regards practical purposes, we may exclude, because it seldom comes under treatment; distention is what we have to deal with when the case comes under our observation. What we see of acute skin diseases, of the diseases of internal organs, and what occurs in fever—all our observations teach us that, in all instances of vascular distention, there invariably comes a period which is essentially one of debility; that we have arrived at a point when nothing further can be gained by depletion; and it is equally true that there is a stage of distention of the capillaries in which, by affording them some relief, they possess of themselves the power of returning to their natural state. This leads me to a distinction of the condition of the capillaries founded on truth—a distinction made by Andral into sthenic and asthenic: in the former the vessels, on being relieved from their distended condition, possess the power of returning to their former healthy state; in the latter, their state of debility is such as to render them incapable of recovering their contracted state by their own efforts. Here, again, pathology comes to our aid; let us look at the distended intestine, in hens, for instance, which affords a beautiful example of these principles. A period occurs in the disease when it is only necessary to relieve the intestine of its distention, and the intestine possesses the power of returning to its original condition; but, later, a period arrives when we must stimulate with wine, brandy, and small doses of opium, when we must both remove the distention and aid the intestine to contract. Thus in this disease you find an illustration of the necessity of two opposite lines of treatment, according to the stage of the disease you are dealing with. As another illustration of the physical condition of the capillary vessels we may take a common elastic tube; if in its over-distended state you afford it relief it quickly returns to its original calibre. In the same way does the capillary vessel regain its natural elasticity if relieved in time; but let the distention be continued in the capillaries from vital, or in the elastic tube from mechanical, causes, it then becomes necessary, in order to restore the vessels or the tube, to act upon them in two ways—to remove the causes of distention, and to restore the original vital or elastic contractility.

Thus, then, viewing the division of Andral, you can understand that condition of the capillaries to which he applies the term sthenic hyperemia, requiring active depletive measures, as blood-letting, tartar emetic, low diet, all those remedies which relieve the capillary system as a whole, and permit the vessels to return to their original

condition. Remove the offending cause, and the part retains power to recover its healthy state. In the treatment the most useful part often consists not in what may be called curing the disease, but in removing the causes of diseased action, and nature will effect the rest. Your views of medicine must be very limited, if you suppose that in using such and such remedies you are doing what is called curing the disease. In acute disease, however, to give the vessels the power of returning to their original condition, it is also often necessary not alone to relieve their distention, but after a time to have recourse to external stimulants and internal tonics, in order to restore the lost tone of these vessels. This is the æsthenic hyperemia of Andral. Take a case of fever, and see what the mode of treatment is. While the local abstraction of blood by leeches is employed for the relief of the cerebral congestion of the capillaries, or in the case of the lungs for a similar purpose, the exhibition of wine and tonics internally is resorted to at the very same time to bring back lost tone to the capillaries of the system. We relieve the distended capillaries by the one means—we increase their tone by the other.

Let me again impress on you this fact, that you cannot possibly understand the compound treatment of inflammatory action, unless you keep constantly in view the divisions into sthenic and æsthenic.

THE CAUSES OF SUDDEN DEATH.

By MALCOLM HILLES, Esq.

(Continued from p. 9.)

Asthmatic affections of the lungs sometimes produce sudden death, although these diseases usually exist for a length of time before they prove fatal. Cases of this kind come so frequently under observation, that it is unnecessary to give details of such.

There is no disease of the lungs, the pathology of which is so misunderstood as that of asthma, or respecting which there is a greater variety of opinion, or in the description of which more obscure language is made use of.

This is a good deal to be attributed to the authors who have written on this subject confounding the causes, effects, and symptoms of the disease with the disease itself, and departing from the only true guide in the classification of disease, namely, pathology.

Dr. Mason Good (a) thus writes:—"Whether the suffocative tightness of the chest be the result of a spasmodic stricture of the bronchial vessels, spreading thence to the muscles of respiration, or produced by an inflation of these vessels from a superabundant effusion from their exhalents, is a question," &c.

Dr. Williams's (b) language is not much more intelligible:—"We have both spasmodic and paralytic affections of other muscular organs and canals—of the bladder and urethra, the intestines, &c.; and analogy favours the supposition that we may have similar conditions of the muscular fibres of the air-tubes."

This is the more strange, as the labours of Renssien, Laennec, and others, have established the presence of muscular fibres, or, at least, of contractility, in the minute air-cells of the lungs, the existence of which explains the phenomena presented by the disease of asthma, this being clearly referable to a morbid or spasmodic state of the muscular or contractile fibres of the air-cells. That the bronchial tubes, as seemingly inferred by Dr. Williams, the laryngeal muscles, the muscles of respiration and respiratory nerves, should gradually participate in the spasmodic action, is reasonable, and what may be expected

in parts so intimately connected both by structure and function.

I have, some years since, brought forward the theory that this contractility of the air-cells was of use, in the natural state, by contracting these cells so as to force the air more completely into contact with the venous blood in the lungs, the oxygen of the air acting as the excitant for this purpose. This theory serves to explain some of the symptoms of asthma, more especially those produced by a highly rarefied or otherwise irritating atmosphere. I shall allude to this theory again, when we come to treat of the effects of carbonic acid and other gases on the organs of respiration.

Some cases of asthma are of course referable to a diseased state of the nervous system, and not to any abnormal condition of the muscular or contractile fibres of the air-cells. But, whatever opinion we may form as to the pathology of asthma, the cause of sudden death, in these cases, is an arrest or stoppage of the act of respiration. This function ceasing, the nervous and circulatory systems soon participate in the morbid action, and their functions cease also. Of these three great functions, the circulatory may be reasonably supposed to be the last to die. Indeed this cannot be a matter of supposition, as the livid state of the skin generally, but more especially the lips and face, the congested state of the eyes, vessels of the brain, and the lungs, establish as a fact the continuance of the heart's action for some time after, till respiration and the nervous influence have ceased.

Some cases are recorded of persons dying suddenly, with asthmatic symptoms, where no disease of the lungs was observable after death, but, instead thereof, some one or more of the neighbouring viscera were found to be in a diseased condition. The heart is usually the organ at fault; but it also occurs where the liver, stomach, or other viscera, are affected. This is a form of disease which puzzles the practitioner a good deal, and leads to much variety of opinion as to its true seat and the immediate cause of the asthmatic symptoms. It is a species of *sympathetic asthma*, and is no doubt induced through the connection which exists between the principal organs of circulation, respiration, and digestion, by means of the pneumo-gastric nerves and the intimate relation of all the functions to each other.

The following case, related by Mr. Greenwood (a) at a meeting of the Physical Society, Guy's Hospital, is an interesting instance of this affection:—

"Mrs. S. has enjoyed good health, and is the mother of a large family. On the 6th of October, 1838, I was called to see her, at four A.M., and found her in a state of insensibility, &c. Her husband stated that she had awakened him, complaining of a difficulty of breathing, jumped out of bed, ran to the window, which she managed to raise, and then fell back senseless. The patient recovered this attack, and remained well until the 24th of November following, when Mr. Greenwood, being called to see her, found her on his arrival quite dead. She had awakened her husband as before, complaining of dyspnoea, and before a candle could be procured she expired. On a *post-mortem* examination, the liver was the only organ found seriously affected, which was found 'enormously enlarged,' so as to encroach on the thoracic cavity superiorly, and the abdominal inferiorly. In the discussion which ensued much difference of opinion as to the cause of the fatal symptoms was manifest."

Dr. Forbes (b) states, "In a case of asthma, related by Ferrus, a large ossification was found in the centre of the pulmonary flexus, which compressed some of the nerves." (*Diet. de Med.* tom. 3.) In a case of fatal dyspnoea, Beclard could discover no cause of the disease, but a tumour on one of the diaphragmatic nerves. A

nearly similar case is related by Andral (*Diet. de Med. Prat.*, tom. 3, p. 109); and Parry mentions a case of dyspnoea, occurring by fits of aggravation, and at last proving fatal, without any symptoms of local pneumonic disease, in a person who had thickening about the upper part of the vertebrae of the neck, with some degree of distortion, from venereal affection." (*Posthumous Works*, vol. 2, p. 16.)

These cases were evidently spasmodic affections, proceeding from contraction of the nerves, connected with the function of respiration, viz., the pulmonary flexus, diaphragmatic and other nerves; but to what structures are we to refer the spasmodic action? If this were situated in the external muscles of respiration and diaphragm, such would be manifest: its seat must have been, then, the muscular or contractile fibres of the air-cells or bronchial tubes; but as these latter are furnished with cartilaginous rings, and, where these are deficient, possess sufficient resistance to prevent their being closed by the muscular fibres to be traced in them, I am of opinion that the principal seat of the disease in such cases is the contractile tissue of the air-cells themselves.

Supposing, then, the air-cells of the lungs to be endowed with muscular contractility, for the purpose, as already stated, of compressing the atmospheric air more perfectly into contact with the venous blood, in healthy or natural respiration, it requires only an increased degree or morbid state of this contractility to induce the various symptoms of asthma, and explain most of the phenomena to be observed in the course of this disease.

The diseases of other organs may excite this unusual degree of contractility sympathetically, and others induce all the asthmatic symptoms, without any appearance of such being manifest on a *post-mortem* examination.

It is most desirable that the pathology of this disease should be fixed, and that our professional works should get rid of the various names attached to its different features or symptoms, rather than the disease itself. This being once accomplished, a defined rational plan of treatment might be laid down for this affection, whether of independent existence or existing in conjunction with affections of the bronchial membrane, heart, or other neighbouring viscera. Sudden death rarely occurs in connection with other diseases of the lungs.

PART II.

ON CASES OF SUDDEN DEATH IN WHICH NO LESIONS OR MORBID ALTERATIONS OF THE LUNGS HAVE EXISTED, OR, IF PRESENT, HAVE NOT CONTRIBUTED TO THE RESULT.

The sudden deaths caused by drowning, strangulation, and exposure to carbonic and other noxious gases, are so intimately connected with this part of our subject that we introduce them here, especially as their consideration will serve to assist in the elucidation of the physiological phenomena that present themselves whilst life is being extinguished from impediments to the function of respiration from various causes.

The principal cause of death in these cases is the sudden arrest of the function of respiration; indeed it has been, and is generally conceived to be, the sole immediate cause; but in this opinion I do not concur, as several phenomena which occur in these cases are quite inexplicable on this supposition; and we know full well that respiration may be voluntarily suspended, for a minute at least, without any serious result; we must look, therefore, to other impressions as contributory at least to the fatal termination.

Death by drowning, as it usually occurs in these countries, is chiefly to be attributed to the sudden arrest of the respiratory function. When an animal, such as man, is immersed in the water, no perfect act of respiration can be performed; the individual endeavours to inspire, but the rima glottidis becomes closed to prevent the ingress of the fluid into the lungs; the individual then expires, and forces out a small quantity of air which appears on the surface of the water in the form of a few bubbles; the attempt

at inspiration is renewed with the same results, and then succeeds a still more feeble effort at expiration; these attempts are repeated a few times, when the person becomes drowned or asphyxiated. In this state the patient continues for a few minutes, before life becomes wholly extinct; the exact time necessary to the complete extinction of life is variously stated, and is no doubt subject to much variety; some assert that three, four, and five minutes are sufficient to produce death, whilst others represent recovery to have taken place after three-quarters of an hour's immersion. Although little confidence is to be placed in most of these statements, it is certain that cases have been recovered where immersion had continued for half an hour at least. Dr. Copland states, (a) "Of twenty persons recovered from drowning, one had been three-quarters of an hour under water, four half an hour, three a quarter of an hour, and the rest for shorter periods." Much of this variety of opinion and experience must be owing to the various impressions made on the individual by the water, and to the health and strength of the person himself. If the temperature of the water be much reduced, say so low as 40° and under, there can be no doubt that the powerful impression made on the skin will contribute to the sudden appearance of asphyxia, and the more rapid extinction of the vital spark; we need not add that an old and unhealthy individual is less likely to sustain immersion for even a short period, than young and strong constitutions. I think I have remarked that suicidal attempts at drowning are more rapidly fatal than the contrary.

Dr. Gregory states (b) that Dr. Davy "informed him that he had not been able to recover dogs that had been under water two minutes, even by means of artificial respiration and galvanism employed immediately;" and also "an animal immersed in a freezing mixture, but with the respiratory organs free, speedily dies."

In cases of strangulation, suffocation is not the immediate cause of death. Where violence is used, death is caused by the concussion propagated to the brain, either directly or through the nerves compressed, or the vessels of the neck distended with blood, all of which are sufficient to cause death, even although respiration were still maintained. The rapid destruction of life caused by the peculiar manipulation of the Thugs in India is evidently to be attributed to some agency of this nature, rather than to the stoppage of the respiration. In most of these cases the sufferer was killed, and at once rendered incapable of making even an attempt at resistance. (c)

In the respiration of carbonic acid gas, death usually takes place too instantaneously to be produced solely by a cessation of respiration; from the following cases it will appear that asphyxia takes place at variable intervals, according to the strength or purity of the gas; death taking place almost instantaneously where this exists in considerable quantity.

In the year 1766, one hundred and forty-six Englishmen were confined in the blackhole at Calcutta, from eight in the morning until the next morning, when only twenty were found alive. A similar instance happened in London in 1742. Twenty persons were confined in the

hole at St. Martin's Roundhouse, of these four were found dead in the morning. In 1813 two lads were found senseless in a brick kiln in St. George's-fields. ("Beck's Medical Jurisprudence" and "Edinburgh Annual Register," vol. 6, part 2, p. 61.)

Dr. Babington relates ("Medico-Chirurgical Transactions," vol. 1, p. 183) the case of a boy and a waiter, who slept during the night in a room where a chafing-dish of charcoal was kept burning. The boy died, after some attempts to restore him; the waiter, however, recovered, but with much difficulty.

In the Grotto del Cano, at Naples, insensibility is rapidly induced in dogs by the action of carbonic acid gas, which collects in the lower stratum of air in the grotto. D'Arceet, visiting the place at Montpenser, in France, where carbonic acid gas issues from the ground, as at the Grotto del Cano, in Italy, attempted to ascertain its effects, but they were so sudden that, having moved towards it on his hands, he instantly fell flat, and would have expired, had he not been drawn back by his guide. ("Beck's Med. Jur.," p. 612.) Sir Humphrey Davy ("Researches concerning Nitrous Oxide," p. 172, and "Ray on Asphyxia," p. 333), having prepared some very pure carbonic acid gas, attempted to inspire it, but it was in vain that he made repeated efforts to draw it into the windpipe. It occasioned such painful irritation as to cause a complete closure of the opening into the larynx. Many instantaneously fatal cases are recorded from the inhalation of carbonic acid gas, collected in brewers' vats, deep wells, graves, &c.

I have related these instances of the various effects of carbonic acid gas, for the purpose of showing that its effects vary considerably, according to its purity or otherwise; and that, therefore, its action on the animal economy depends on the degree of purity of the gas in use.

This is an important physiological fact, which has not received sufficient attention; much error and much difference of opinion being the result. Thus Bichet and Nysten ("Recherches de Physiologie et de Chimie Pathologiques") were led by their experiments to conclude that carbonic acid gas is not more deleterious in its effects, when inspired, than nitrogen or any of the negative gases.

M. Colland de Martigny ("Archives Gen. de Médecine, Juin 1827," t. 3, p. 91) has proved that it has a remarkable sedative influence; in this opinion he is supported by Dr. Bird ("Lond. Med. Gazette," vol. 2, 1838-9, p. 25), who has shown that the effects of this gas vary according to its purity and degree of intermixture with the atmospheric air. In five per cent. of carbonic acid, mixed with atmospheric air, death was produced in a bird in one hour. The same kind of bird, when placed in pure carbonic acid gas, immediately asphyxiated. M. Colland de Martigny and Dr. Bird both regard this gas as a direct poison.

The cases I have detailed show that its action is that of a sedative, or narcotic, when inhaled in a moderate state of purity, the exact proportion necessary to act thus, varying, of course, with the animal acted upon; whilst it will act as a more active poison and irritant, if inhaled in a pure state. In what manner, then, is death produced by the inhalation of carbonic acid gas?

In those cases where the gas is mixed with a certain portion of atmospheric air, death seems to be produced by its acting as a sedative or narcotic poison on the system. All animals, so exposed to its effects, fall gradually into a state of sleep or stupor, which continues until death supervenes, or recovery takes place. The narcotic effect continues for several days. In the case of the waiter, related by Dr. Babington, the patient did not recover his senses till the third day had elapsed, and then could only recollect to mind the circumstance of the charcoal burning brightly shortly before he fell asleep. There is a striking analogy between this state and that of patients labouring under difficult respiration, in which coma takes place, when the disease becomes much aggravated. In both cases the cause of death is

similar: the carbonic acid gas collects in the system until it paralyzes the brain and nerves, and thus leads to a stoppage of the circulation and circulation. I place circulation last in order, as the experiments of Bichat (a) have shown, contrary to the opinion supported by Godwyn and others, that the heart continues to contract and the circulation is kept up for a considerable time after respiration has ceased, notwithstanding that black or venous blood circulates in the left cavities of the heart and arterial system. In cases, however, where the carbonic acid gas is present in larger quantities, as in brewers' vats, deep wells, graves, &c., death takes place so instantaneously that we must refer its occurrence to a morbid impression on the nervous system, the gas thus acting as a highly concentrated poison of a narcotic and irritating nature.

I cannot but consider that the morbid impression exercised on the mucous membrane of the air-cells of the lungs, by the carbonic acid gas coming into direct contact with the extremities of the nerves, is the principal source of the rapid asphyxia that takes place in these cases.

If we reflect on the extent of this mucous surface, certainly much greater than that of the whole cutaneous surface of the body, it will not appear extraordinary that such violent effects should result from contact of a mephitic gas, such as the carbonic acid.

Physiologists are gradually becoming more convinced that it is on the extremities of the nerves that agents produce the most decided results, and that the intermediate portion of the nerves are little affected thereby, the part being, *per se*, almost, if not wholly, insensible. This opinion is strongly supported by the fact that all impressions made on the trunks of the nerves are felt at, and referred to, their sensitive extremities; the feeling which appears to continue this action in cases of amputation of the limbs or divisions of the nerves does not negative this fact, as such may be accounted for on the theory that the nervous trunk continues to sustain an action to which it had long been familiar, and which, however false, takes a considerable time to remove. This power of the nerves of the extremities seems to be closely analogous to the power preserved by blind persons, of recalling the impressions of objects to the mind long after the sensibility of the retina has been lost. But some will perhaps state, in opposition to this doctrine, that the cutaneous surface of the body may be exposed to this and other gases with impunity. To this I reply, the cases are not analogous; animals may be poisoned by the application of carbonic acid gas to the skin only; the skin is less delicate than the mucous surface of the air-cells, is covered by the cuticle, and is constructed so that its nervous filaments may be subservient to the sense of touch, and but little affected by agents which operate powerfully on other tissues. Each organ seems to be most sensitive to its own immediate excitant; thus, for example, light is the peculiar excitant of the eye; sound, of the ear; food, of the stomach; air and gases, of the mucous membrane of the lungs. How inefficient would these agents be, if applied to other than their peculiar organs! Each is naturally sensible to its own excitant, and is morbidly sensible to its injurious operations. This principle is well displayed in the action of medicines on the human economy: one acts on the stomach alone; another on the small, a third on the large, intestines; others on the brain, the heart, the liver, &c.; these being the natural excitants of these parts. There is no peculiarity in the structure of these several parts, to explain such results; the only explanation available, if it can be called such, being that such is the law of Nature. We may reasonably conclude, then, that carbonic acid and, most probably, other mephitic gases exercise a peculiar morbid influence on the nervous expansion, distributed on the mucous surface of the air-cells.

(a) "Diet. Practical Medicine," Art., "Asphyxia," p. 132.

(b) "Elements of the Theory and Practice of Physic," 1828, p. 473.

(c) Where violence has not been used, death from strangulation is to be attributed to arrest of the function of respiration, succeeded by a congested state of the vessels of the brain. This opinion is confirmed by the experiments of Gregory and Brodie, from which it appears that if an artificial opening be made into the trachea of an animal, below the ligature by which it is suspended, it will continue to live for a considerable time. Sir B. Brodie has not omitted to observe on the injury done in these cases to the pneumo-gastric nerves.

each being the natural, although morbid, result of their peculiar function. If such be the case, we can have no difficulty in accounting for cases of instantaneous or sudden death, produced by the inhalation of this gas, and which cannot be explained on any other theory that I am aware of.

In Sir Humphrey Davy's attempt to inhale the carbonic acid in its pure state, the glottis became immediately closed, the poison in this case acting as a direct irritant. It is to be observed, that no bad effects resulted, although respiration was stopped; had the gas entered the lungs, Sir H. Davy might have suffered severely for his temerity. In a less-concentrated form, might not the gas act as an irritant on the contractile fibres of the air-cells, although not sufficiently powerful to produce such an effect on the muscles of the glottis? When treating of sudden death from asthma, I explained the theory I have advanced regarding the use of these fibres, and can easily conceive a spasmodic condition being produced in them by the action of concentrated carbonic acid gas, so as to resemble an attack of spasmodic asthma.

The morbid impressions made on the skin when an individual is immersed in the water seems analogous; in both, the impression is made on the surface, and is thence transmitted to the brain directly through the agency of the nerves, without any necessary intervention of the vascular system.

I do not understand why all impressions made on the nervous extremities should be referred to the sensorium. I have long since advanced the doctrine that the ganglionic expansions of the nervous filaments may act as sensoria, and that impressions may be produced there, and propagated to the anastomizing filaments of the nerves, so as to excite these to action, ultimately the impression reaching either the brain or spinal marrow, thus establishing the nervous anastomoses and several plexuses as sensoria, independent of the brain in action, but dependent on it for the integrity of the function. This doctrine may appear to be similar to the views propagated by Dr. Marshall Hall on the nervous system; it differs, however, in many respects, as will be evident on comparing these together, the principal point of difference being the independent action of the medulla oblongata, which Dr. Hall contends for, and which, notwithstanding my respect for this gentleman's extensive researches and elaborate reasonings, I cannot consider as existing in man, or at all necessary in the physiological phenomena I allude to, except as a connecting medium.

The rapidity with which death takes place in these cases leads us to the conviction that the cessation or sudden stoppage of the act of respiration is not sufficient to account for such phenomena, and that there must be some other agency, as already stated, in operation to produce so rapidly fatal results.

Let us suppose for a moment, as is the general opinion, that the venous blood, not being arterialized, circulate through the vessels of the brain, and thus induces asphyxia. If we reflect a little, we shall see that this explanation is far from correct. The blood, thus unarterialized, cannot possibly reach the brain until after several pulsations, and then only in a mixed state. As the left ventricle does not propel more than four ounces of blood at each pulsation, several pulsations will be necessary to empty the pulmonary veins of the arterialized blood previously contained in them; let us suppose this quantity to amount to the comparatively trifling estimate of twenty ounces, it follows that five pulsations must take place before any portion of the unarterialized blood can enter the heart; after these, some, but mixed with partially arterIALIZED blood from the capillary veins, will reach the left auricle, whence it is propelled into the left ventricle, and thence into the arterial system; but here, also, some delay takes place, inasmuch as the arteries do not empty themselves of their contained blood at each contraction of the heart; and, consequently, the unarterIALIZED blood

cannot reach the vessels of the brain until some few more pulsations take place; let us estimate these at five also, on the supposition that it takes this number of pulsations to fill the whole arterial system, we shall have ten pulsations as the number requisite before the unarterIALIZED blood can reach the brain, so as to produce the effects on this organ generally attributed to it; but this supposition is opposed to facts, as asphyxia is often produced instantaneously, whilst, as I have shown, ten seconds are required for the unarterIALIZED blood to reach the brain—a space of time sufficient to allow of the patient making some effort to escape, or some attempt at alarm. But may the patient respire the gas for this period of time without being conscious that this is the case, and only exhibit its effects at the precise period at which the unarterIALIZED blood reaches the brain? The history of these cases negatives this supposition, and shows that the asphyxia is produced at the first act of inspiration.

Bichat, in his celebrated work on "Life and Death," (a) has induced the profession to regard this impression on the brain, by the circulation of the dark-coloured blood, as the chief source of asphyxia. I think this opinion cannot be maintained. I conclude, then, that the simple arrest of the act of respiration (b) is not sufficient to account for the suddenly fatal termination of the cases we have described, and that a more rapid impression on the constitution exists, and is necessary to produce such results; this I consider to be the sudden impression on the sensitive extremities of the nerves, produced in asphyxia from carbonic acid gas, by the contact of the gas itself; in drowning, by the contact of the water at a cold temperature; and in rapid strangulation, by the concussion on the nerves of the neck, immediately transmitted to the sensorium.

When we come to consider the phenomena produced by the action of prussic acid and other powerful agents on the system, we shall be able to show that these support very much indeed the theory I wish to establish, namely, that of the sentient extremities of the nerves being so susceptible of a powerful morbid impression, which is independent of the brain in its immediate action.

• (a) "La Vie et la Mort."

(b) The very remarkable case of the Honorable Colonel Townshend, related by Cheyne, serves to prove that the act of respiration may be suspended for a considerable time without destruction of life. The following is Dr. Cheyne's account of this singular case ("English Malady," p. 307):—

• He told us he had sent for us to give him some account of an odd sensation he had for some time observed and felt in himself, which was, that, composing himself, he could die or expire when he pleased, and yet by an effort, or somehow, he could come to life again; which it seems he had sometimes tried before he had sent for us. We all three felt his pulse first: it was distinct, though small and thready, and his heart had its usual beating. He composed himself on his back, and lay in a still position for some time; while I held his right hand, Dr. Baynard laid his hand on his heart, and Mr. Skeine held a clean looking-glass to his mouth. I found his pulse sink gradually, till at last I could not feel any by the most exact and nice touch. Dr. Baynard could not feel the least motion in the heart, nor Mr. Skeine discover the least soil of breath on the bright mirror he held to his mouth. Then each of us by turns examined his arms, heart, and breath; but we could not by the nicest scrutiny discover the least symptom of life in him. This continued about half an hour. As we were going away (thinking him dead) we observed some motion about the body, and upon examination found the pulse and the motion of his heart gradually returning; he began to breathe gently and speak softly." The patient died the same evening.

(To be continued.)

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF MEDICINE.

Meeting of March 2; M. BEGIN in the Chair.

ETHEREAL INHALATION.

M. Gérardin stated that he had found a letter addressed to the late King Charles X. by a Dr. Hickman, and dated the 26th of September, 1828. In that letter the author recommended the inhalation of several vapours for the purpose of producing unconsciousness during surgical operations.

A favourable report was read by M. Dubois (d'Amiens), on a paper by Professor Trousseau, in which the treatment of organic stricture of the œsophagus, by dilatation, is specially recommended.

PARISIAN MEDICAL SOCIETY.

Meeting of March 3; Dr. SHRIMPTON in the Chair.

CARCINOMA, BY M. PIGNE, CURATOR OF THE MUSEE DUPUYTREN.

Setting aside the microscopical study of carcinoma, that disease may be considered as a malady, the forms of which differ not in nature, but merely on account of their peculiar seat. Cerebriform cancer, the only variety observed in childhood, is special to the cellular tissue; gelatinous cancer, to lamellar structures; scirrhus, to parenchymata; and fungus hæmatodes, to capillary organs. Cancerous growths should be studied in their texture—in their juice, their pigment, and their peculiar mode of circulation.

1. Carcinomatous texture is a special heteromorphous tissue, of a white colour, and furnished with arcolar, more or less considerable, according to the variety observed; all these arcolæ communicate with each other, and are formed of solid, dense walls, to which the consistency of the tumour must be referred. The lobes are surrounded with cellular capsules, and fibrous bands irradiate in every direction, penetrating the neighbouring parts, and endowed with the property of causing reproduction of the disease, and that within fifteen or twenty days after operation, under the influence of a particular cause hereafter to be noticed.

2. Within the cells is deposited a secretion, the cancerous juice, which increases in abundance with the age of the growth. This fluid is whitish, slightly opaque, and presents a blue tinge, which permits it to be not inaptly compared to the blood of certain molluscs. Very soluble in water, the cancerous juice is, on the contrary, condensed and solidified by pure spirit, and its absorption into the system renders the disease general. In consequence of the communications existing between the cells, the juice readily escapes through any ulceration or aperture, without, however, the bulk of the tumour being thereby diminished, the solidity of the cellular walls keeping them, although partially void of their contents, in a gaping condition.

3. The pigmentum, when concentrated, is of a darker colour, but when disseminated in the tumour and mixed with the cancerous juice, it communicates to the latter a yellowish hue, which absorption disperses through the system, thus producing the characteristic tinge observable in the skin.

4. When considered in combination with the reproduction of cancer, the history of its circulation is highly interesting. In the article "Cancer" of the "Diction.," in vol. 25, Professor Bérard asserts that cerebriform cancer contains numerous vessels, but that none exist in scirrhus. This assertion is disproved by the energetic vitality of the growth, which is perfectly incompatible with the absence of a vascular system: it may be said, however, that the vessels of cancerous tumours do not resemble those of the healthy parts of the body. They first appear in the centre of the morbid product;

they are not veins, for they are unfurnished with valves; they cannot be called arteries, because when divided they collapse. These vessels—the only order of vascular texture proper to carcinoma—seem to hold an intermediate position between veins and arteries. For a long time these vasa propria do not communicate with the general circulation of the subject, hence for a time the disease remains local. When the vessels of cancer resemble more closely those of general circulation, the fact may be considered as a proof of the maturity of the tumour, and of the imminence of diathesis. The blood contained in the vasa propria is almost colourless, and bears a certain resemblance to the blood of mollusca. Inflammation of the cancerous growth promotes the softening of the tumour, but does not tend to increase its size; inflammation of the surrounding parts has a directly opposite influence, increasing the magnitude of the tumour, without modifying its density: hence, if a cancer be not removed in totality, the local inflammation consequent upon operation tends to develop those parts which have not been taken away: hence, also, the precept of Dupuytren and Samson, to operate without delay on each recurrence of the malady, and to display as much tenacity in the determination to destroy the disease, as the disease itself shows obstinacy in its recurrence. The following case is interesting in many respects:—

CASE.—In the year 1834, Mr. B. came to Paris for the purpose of undergoing operation for a cancerous tumour of the orbit: the growth had acquired the size of the head of a fetus. Pains in the limbs and some degree of previous paralysis, showing that the brain was in all probability implicated, induced Professor Samson at first to set aside all idea of an operation. But, the patient having expressed his settled determination to destroy himself if the operation was not proceeded with without delay, M. Samson consented to operate in the presence of several British practitioners, fellow-countrymen of the patient. A portion of the frontal, the nasal, and maxillary bones having been removed, the dura mater was found to be affected, and was likewise excised. But the cerebral substance itself was occupied by the disease, and after a short conference, in which Samson alone persisted in the opinion that it was his duty to achieve the operation he had begun, one ounce and a half of cerebral substance was removed by a section which penetrated into the lateral ventricle. The cerebral vessels were cauterized with a heated probe, and the patient recovered completely from the effects of this tremendous operation—no paralysis, no disturbance whatever of the cerebral functions, having been observed. Sixteen months after, the patient died in consequence of reproduction of the growth in the scar, and on dissection the disease was found to extend as far as the posterior cerebral lobe.

FACULTY OF MEDICINE.

LECTURES ON GENERAL PATHOLOGY, BY PROFESSOR ANDRAL.

A general diminution of the temperature of the body during the progress of disease is very seldom observed; even when a fatal termination is fast approaching, the temperature of the axilla is still found at or above the physiological limit. In one malady only can a notable diminution of heat be observed in all parts of the body. This malady is, therefore, an exception—it is *sclerema*, or induration of the cellular tissue—a disease special to infancy; in this malady the thermometer falls to a very low point (28° , 26° , $23^{\circ}.5$, Cent.; or $82^{\circ}.4$, $78^{\circ}.8$, $72^{\circ}.4$, Fahr.); $23^{\circ}.5$ is the lowest temperature observed, and the disease is preceded by this diminution of animal heat. In cholera the temperature of the limbs, and even of the tongue, undoubtedly descends; but, unfortunately, during the epidemic of 1832, no thermometric observations were taken in the axilla. About two years since, a case of cholera occurred in our practice; the temperature of the limbs was 26° (78°), and of the axilla 38°

($100^{\circ}.4$). In tubercular disease, in anemia, chlorosis, scurvy, &c.,—in all which it would seem natural, from the imperfection of pulmonary hematoses, or the decrease of energy of all the vital functions, to suppose that the temperature of the body is below its average standard. Such is not, however, the case: it remains at its physiological level, and even rises when febrile excitement is present. The same may be said of diabetes, emphysema pulmonis, and prolonged convalescence. In *sclerema* only has the temperature of the axillary region been known to fall (the discovery of the fact is due to Dr. Rogée); and, perhaps, in Asiatic cholera the same fact will be observed, but at present we possess no positive proof of the supposition.

Inanition, consequent upon prolonged abstinence, causes, as it appears from M. Chossar's interesting experiments, diminution of animal heat. When animals are deprived of food they undergo a daily and successive refrigeration of $\frac{1}{8}$ of a degree C (0.51° F.); and when the animal, after feeding upon his own substance, at last collapses, the remaining heat of the body suddenly falls about 11° , and descends to 18° . When this is observed, death may be constantly expected within a limited number of hours.

In plethora and apyretic affections the thermometer is never observed to rise above the highest point noticed during health, i. e., 38° ($100^{\circ}.4$). M. Prevost, of Geneva, has, however, mentioned a case of tetanus, in which he found 41° ($105^{\circ}.8$). But we think we may almost positively assert that fever was present. Let us, however, say that the anatomical seat of tetanus is evidently the spinal chord, one of the principal agents of the production of animal heat; that tetanus is marked by violent muscular contraction, which we know to cause development of heat; and we may therefore inquire if these two circumstances might not, in tetanus, explain, without fever, the increased production of heat.

The partial increase of the temperature of the body is observed on the surface of inflamed organs. It may be established as a general principle that the heat of inflamed surfaces is greater than that of healthy parts, but is never more considerable than that of the axilla of the same subject. This principle has been also demonstrated by Hunter, who established a true result on observations which were not very conclusive: having punctured a hydrocele, Hunter placed a thermometer in the tunica vaginalis, and found it rose to 38° ($91^{\circ}.4$). A few days afterwards, when inflammation had set in, the temperature of the part was again observed; it had risen to 36° ($96^{\circ}.8$). This is the only experiment of Hunter on man which did not yield a negative result. That same illustrious observer, having stimulated with mustard, ginger, and other irritating substances, the rectum and vagina of an ass, found that the process occasioned a rise of one degree in the temperature of the parts. In cold blooded animals, Hunter experienced great difficulty in determining any appearances comparable to inflammation; he never succeeded in detecting any increase of general or local heat. In general the temperature of inflamed parts rises from half a degree to two, but is never superior to that of the axilla. Becquerel and Breschet, on an inflamed tumour of the neck of a patient stated to be in high fever, observed the thermometer to rise as high as 40° (104°) on the surface of the tumour, whereas in the mouth it remained at $37^{\circ}.5$ ($99^{\circ}.5$). This result we cannot accept: the mouth is not a fit place for observation, on account of the continual passage of air, and evaporation which takes place in consequence.

The congestion necessary for the accomplishment of a function is said to cause development of heat. Sir Everard Home found 2° more than in the neighbourhood of the heart, in the oviduct of frogs, near the spawning time. During parturition, the temperature of the womb is said to increase.

Diminution of temperature in a limited part of one tissue may result from four distinct causes.

1. From arrest of circulation.
2. From the appearance of gangrene.
3. From paralysis: and here, besides the withdrawal from the diseased part of nervous influence, abolition of motion and diminution of the activity of nutrition concur to bring on decrease of heat. In a recent inaugural thesis, lately published by Dr. Rontier, the interesting fact is proved by numerous observations, that in the paralysed extremities the temperature is decreased two hours after the accident, but rises above the physiological standard twelve or twenty-four hours later.
4. Oedema of any part also tends to diminish its natural heat.

The study of animal heat forms an easy transition from the inquiry into those properties special to organized bodies, to the investigation of those which living enjoys in common with inorganic matter. One of the most important of the latter is undoubtedly electricity, the sources of which in our system are exceedingly numerous. Thus free electricity is evolved in the multitudinous chemical actions which are perpetually performed within our body; it is produced by the movements, the frictions, which our parts continually undergo. But whilst in all animals a special apparatus exists for the production and disengagement of nervous power, none can be detected, at least in the human frame, for the liberation of electricity. The production of this fluid in living bodies is most variable, and from its varieties may arise some elements of disease. Further than this assertion, all is purely hypothetical, and founded upon facts incompletely observed, and consequently of very little value. Berlinghien endeavoured to ascertain the presence of free electricity in the blood, and asserted that its quantity was diminished in inflammatory affections; increased, on the contrary, in maladies of an opposite nature. Researches of this kind must, however, be made with a degree of delicacy which authorizes us to pause ere we adopt the results of Berlinghien's experiments.

The laws of gravity, in living bodies, exercise their sway within certain limits. Their power is more evident according as the structures are more deeply altered, the vital properties less energetic, and the obstacles to the return of venous blood to the heart greater. The veins, the capillaries, the cellular tissues and the serous cavities, are the parts in which its phenomena are the most distinct.

Thus in the veins, when they have lost their tonicity, when they present obstacles to the free return of the blood, that fluid obeys the laws of gravity: in the capillaries the same is observed, peculiarly in the inferior extremities of debilitated subjects. We may notice a phenomenon of the same kind in the capillaries of the face of subjects weakened by disease; again, in hypostatic congestion of the lung, or in the enlargement of the liver consequent upon disease of the heart, &c., during the last moments of life, and even after death, so long as the blood remains in a fluid state, the intestinal mucous membrane is also the seat of accumulation of that liquid, from the operation of the same cause. The phenomena of oedema, and those physical signs which permit us to detect dropsy of the serous membranes, can serve to illustrate the effects of the force of gravity in cellular tissues, and on the serous cavities of the body.

The continual processes of evaporation, of endosmosis and exosmosis, and of capillarity observable in the system, can, by their disturbance, occasion the development of various morbid elements, which also deserve our attention.

Besides these general physical operations, other phenomena must be taken into account, which depend upon the special properties each tissue is endowed with. Thus the extensibility natural to cellular and fibrous textures, the elasticity proper to the yellow fibre, to fibrocartilage and to cartilage, to the bronchial apparatus, may all be more or less modified by disease, and become the origin of new morbid appearances. Need we add that chemical causes may

likewise occasion the functions to deviate from their healthy and regular accomplishment. Thus the presence of pus in the urine from vesical catarrh, for instance, renders that fluid alkaline, and may give rise to phosphatic deposits and the formation of calculus in the bladder. In the present state of science, disease cannot be properly studied without the full and intelligent appreciation, not only of the vital alterations of the body, but of the numerous chemical and physical operations of which it is the seat.

Few diseases are constituted by one only of the alterations we have laid before you: neuralgia is one of those few; sensibility alone, in that pathological form, appears to have undergone any change; but in general a malady is the result of the combination of several elements, whether they have originated from one, or arisen simultaneously in the system.

In certain cases, disease can be readily traced to a local origin—to a circumscribed dynamic—anatomical or chemical disturbance; disease is there termed local; but in other instances a simultaneous disorder seems to arise in various parts under the influence of a universal cause: such are the alterations of constitutional syphilis; disease then receives the denomination of general.

It is the special property of that force which regulates living bodies, to establish a connecting link between their various functions, to unite them so as to form a whole; hence in the healthy or diseased organism no one point can suffer without its sufferings being more or less distinctly re-echoed in all the other parts of the system. This property essentially distinguishes organisms from inorganic substances, and constitutes the share of vitalism in physiology and in pathology; and the object of the physician must be to establish the laws of life, as it is the object of the chemist or natural philosopher to establish those of affinity and of electricity.

The elements of disease are, therefore, the alterations of the physical or of the dynamic conditions of our organs. The elements can combine *ad infinitum*; observation, however, shows that in most cases they are associated so as to produce a certain number of abnormal states,—which are endowed with almost similar characters,—and resemble each other by their mode of development, of succession, of termination; observation likewise teaches us, that in general they yield to the same therapeutic agents; whenever, for instance, under the influence of cold, accumulation of blood takes place in the lungs—whenever they become the seat of fibrinous or purulent deposits, when at the same time febrile excitement appears, together with an increase of the average amount of fibrine contained in the blood—experience shows that venesection is profitable. When the same phenomena occur elsewhere, the case is not changed; setting aside the nature of the diseased part, the pathologist constitutes from the association of the circumstances enumerated a whole, which he terms a disease, and to which, according to its degree, he imposes the appellation of "hyperemia" or "inflammation."

A certain number of groups can thus be formed, and a division of the morbid elements into classes from their resemblances, or from their disparities. Hence the artifice of nosological classifications—an indispensable but recent process, which was first attempted two centuries ago. This division of diseases is essentially temporary, and can be considered complete only when science itself shall have ceased to progress.

MADAME HAHNEMANN AND THE POLICE CORRECTIONELLE.—The widow of the celebrated father of homœopathy has been condemned to 100 francs fine for illegal practice of medicine. The amount of the penalty may appear "minutesimal," but a second condemnation subjects the culprit to personal imprisonment.

The *projet de loi* on medical practice and instruction, presented to the Chamber of Peers and Deputies, excites in the profession considerable disappointment and discontent. A protest, signed by a very large number of physicians and

students in medicine, was handed to the Prince de la Moskowa, son to the late illustrious and unfortunate Marshal Ney, and the noble peer promised to support the petition in the Upper House.

D. MCCARTHY, M.D.P.

GERMANY.—ON SPERMATORRHOEA, by Dr. H. Kunkel, Pupil of Lallemand. The effects of this malady on the economy are first carefully examined. Mental alienation of different forms are frequently complicated with spermatorrhœa. Seminal weakness arises from various causes. Irritation advances from the urethra gradually towards the testicles, the secretion of which becomes augmented. The seminal fluid, imperfectly elaborated, is scarcely arrived in the seminal vesicles, which have become extremely irritable, before they eject it, the ejaculatory canals having lost the power of retention. All the phenomena attending the normal ejection, erection, orgasm, and erotic thoughts, disappear. There is simply excretion of a thin fluid, without any symptom of excitement peculiar to the genital organs. Cauterization of the prostatic surface is sometimes, though not always, beneficial; but it must not be rashly employed without regard to the *Alutia magni momenti*.

Great Britain and Ireland.

DISSECTION OF THE EARS OF A DUMB AND DEAF PERSON.—RIGHT EAR.—The meatus externus is full of cerumen of a dark-brown colour. The membrana tympani is of a dull white, and somewhat thicker than natural. The epithelium covering its external surface is denser than usual, and its internal mucous layer thick and soft. The cavities of the tympanum and mastoid cells are completely filled with a secretion of a leaden-white colour; it is thick, and in some parts rather viscid. On microscopic examination it was found to consist chiefly of pus globules pervaded with granules, characteristic of serofulous matter. The mucous membrane of the tympanic cavity is much thicker than natural; it is very soft, and contains large tortuous vessels full of dark-coloured blood. The ossicles are quite enveloped, and in a great measure concealed from view by this thick membrane. The only part of the stapes discernible is the point where it joins with the incus. The Eustachean tube is healthy; the auditory nerve and cochlea quite healthy; the fluid in the vestibule and semicircular canals transparent; but the membranous labyrinth is rather thicker than natural, and under the microscope it is seen to contain numerous blood-vessels; the superior semicircular canal is incomplete at its posterior half, and the posterior canal is almost wholly absent. The left ear was in a similar state to the right, excepting that the external meatus is slightly contracted, and the layer of bone separating it from the mastoid cells is partially absorbed at the posterior surface of its internal extremity for a space of five or six lines in circumference. The membrane covering this portion of bone is thick and vascular, and its blood vessels directly communicate with those of the mucous membrane of the mastoid cells.

I have observed an absorption of the layer of bone between the external meatus and mastoid cells in other in other instances, and in one dissection the cerumen was found projecting from the cavity of the meatus into the mastoid cells. It is not improbable that the absorption of the bone is constant pressure of hardened cerumen. The superior semicircular canal was almost wholly wanting.

OBSERVATIONS.—There can be no doubt that the cause of deafness in the patient from whom the ears were taken was the deficiency of the semicircular canals, but it is interesting to notice the thickened condition of the mucous membrane of the tympanic cavity, and the presence of the purulent matter. From the dissections I have made during the last seven or eight years, which amount at the present time to 511, it is quite apparent that the most frequent cause of deafness is a morbid

condition of the tympanic mucous membrane. In some instances there are bands connecting various parts of the tympanic cavity together, and preventing the natural motions of the ossicula and membrana tympani; in others the cavity is nearly filled by the thickened membrane, and very often there are large quantities of thick viscid matter, which I have every reason to believe may remain for many years if not affected by medicinal agents. A great number of this kind originated in serofulous inflammation. It is also interesting to remark how rarely the Eustachian tube is affected. I hope, ere long, to lay before the medical profession the results of some of my later investigations into the nature and treatment of diseases of the ear.—*Mr. Cross, of Norwich, in Provincial Medical and Surgical Journal.*

USE OF TARTAR EMETIC.—In children, especial regard should be had to their constitutions. In those naturally delicate, and especially where the serofulous diathesis exists, it should never be used if it can be avoided. Prostration is much more apt to ensue in them, and where the article is persisted in for any length of time, it is sure to do harm. It is in such constitutions, when labouring under hooping-cough, and where the use of this article has been too long continued, that the baneful effects of it are most strikingly observed. It is perhaps hardly necessary to say, that if tartar emetic be an article of such danger, the younger the subject to whom it is given, the more likely is it to do harm. In children under a year, I should say, as a general rule, it ought never to be used. During that period, the powers of life are too feeble to bear so active a remedy, at the same time that all the beneficial effects of an emetic may be gained from the use of ipecacuanha, or even milder means.

An engorged state of the uterus is very liable to alternate with, translate to, or coexist with, congestion of the liver or spleen: a fact that ought to be borne in mind, as these states set in so rapidly at times as to render them difficult to discuss, and more particularly, if our patient be worn out by the disease and reduced by the treatment, it places her in a very unfavourable position for bearing the discipline which this new complication demands. Leeching and counter-irritation, with mercurial alteratives, must be had recourse to, for the organs secondarily engaged; but what we have derived the most marked benefit from, under these circumstances, has been a course of Pullna water and taraxacum, followed by the discutient waters of Germany, change of air, and the use of the Russian bath.

—*Dublin Quarterly Dr. E. Kennedy.*

PATHOLOGICAL SOCIETY.—JAN. 16.

Dr. HUTTON in the Chair.

Dr. Law presented a specimen of acute ulceration of the larynx that had occurred in a man, aged sixty-eight, a shoemaker by trade. Six months before coming under Dr. Law's notice the man said he had sore throat, which he attributed to his having used his voice rather freely, for it appeared the man had been a noisy politician.

On admission to Sir P. Dunn's Hospital his most prominent symptom was complete aphonia, his voice being reduced to a low, scarcely-intelligible whisper; his breathing was loud and stridulous, and attended with extreme embarrassment. The character of the respiration so closely resembled that occasioned by the pressure of an intro-thoracic tumour upon the trachea, that Dr. Law at once directed his attention to ascertaining the existence or otherwise of such a tumour; but he found no fulness about the throat such as usually accompanies those tumours, nor was there any turgescence of the vessels of the neck, or any trace of dulness at the top of the sternum. Next, the infra-clavicular regions were examined, with a view to ascertain how far the feeble, impeded respiration might not be connected with dulness in those regions; but here also there was no physical

evidence of disease; so Dr. Law concluded that the case was one of pure laryngeal disease.

On making particular inquiry as to whether the patient had ever been affected with *sypilitic* disease, he said he never had. When the finger was passed along the tongue the epiglottis was felt standing up and much thickened. The patient's greatest distress was referred not so much to the larynx (which was sore on pressure) as to the top of the sternum, where he described a choking sensation from the difficulty of expectorating the mucus accumulated there.

The treatment consisted of local bleeding, blisters to the throat, and mercury; occasional emetics also were administered, and afforded him much relief. The man became so much better that Dr. Law was rather surprised at the case taking a suddenly unfavourable turn.

He was subject to occasional attacks of suffocation, particularly at night; and in one of these he died.

Specimens of what may be called idiopathic or original, primary laryngitis are, Dr. Law observed, rarely met with; and here we have a considerable portion of the mucous lining of the tube deeply ulcerated, particularly occupying the ventricles, and extending on each side. The epiglottidean fold was much thickened, as also the epiglottis itself. A triple lesion existed here, viz., ulceration, oedema of the glottis and of the epiglottis, and diphtheria or effusion of lymph. He had on a former occasion exhibited to the society a specimen of extensive ulceration of the larynx in a case in which there was oedema and ulceration of the glottis. The case was one of pemphigus gangrenosus, supposed to have resulted from an animal poison: the patient when alive having presented every appearance like the result of an animal poison, and, although he had not come into direct contact with such a source of disease, yet there was a glandered horse in an adjacent stable.

There was one point, dysphagia, as connected with aneurism which Dr. Law felt anxious to allude particularly to, and which he had omitted to do on the last day, on which occasion, it would be remembered, he had brought forward a case of aneurism of the ascending aorta. In aneurisms of the latter class it would be found, he believed, that difficulty of respiration would be the prominent symptom; while, in aneurisms of the descending aorta, the oesophagus being placed between the aneurisms and trachea, the difficulty of respiration would be less, and the dysphagia greater.

The coincidence of dysphagia and aphonia favoured the diagnosis of laryngitis as contradistinguished from oesophagic tumour; the dysphagia, not being a remarkable symptom, shows the aphonia depends on pressure from tumours, as in such cases the intestinal trachea protects the oesophagus.

Dr. McDonnell laid before the society a preparation taken from a person who died in the Richmond Hospital two months ago of strangulated congenital hernia in a state of sphacelus. The strangulation occurred on a Saturday, and the patient was admitted into the hospital on the following Tuesday. From the symptoms present immediate operation was decided on. The tumour was at the right side, about four inches in length, running in a line with Poupart's ligament, and its breadth in a direction at right angles with that ligament was two inches and a half; it was of a dingy brownish red colour, and, at one part, light pressure showed it to be slightly oedematous; the integument did not roll over the tumour, so that it was evident the parts beneath were matted together by lymph. These particulars, in reference to the tumour, Dr. McDonnell was anxious to direct attention to as indicative of the state of things within, and enabling one to draw correct conclusions in cases of that particular kind; moreover, he (Dr. McDonnell) was of opinion that the symptoms, as laid down in books for our guidance in such cases, are void of real practical value; the symptoms upon which most stress is laid as indicative of the occurrence of sphacelus being an apparent

amelioration of the case, a cessation of pain and vomiting, with other general signs of improvement; while, at the same time, the countenance becomes hippocratic; cold sweats occur, with feeble, intermittent pulse.

Now, of three cases which came under his (Dr. McDonnell's) own care, and in which sphacelus occurred, not one of these symptoms was present, but the tumour had the characters above described, viz., the matting together of the coverings of the tumour; the skin, on endeavouring to move it, would not roll under the fingers, and when the first incision was made it did not fly open like healthy skin. The incision was linear, in accordance with the condition of the parts described, and which might lead at once to a suspicion of the true nature of the state of the internal structures. Besides these, the dingy red colour of the skin, and the oedema, all taken together, proving the presence of effused lymph matting together the parts lying between the integument and intestine.

On cutting into the tumour in the foregoing case, Dr. McDonnell found the deeper parts confounded with each other in such a manner as to render it almost impossible to distinguish the different structures, but it was quite evident that the sac lay in the inguinal canal, and that it was a hernia by oblique descent, with the hernial sac extending to the lower extremity of the inguinal canal. As the sac was approached there was an obviously gangrenous tendency exhibited; the dark fibres of the internal oblique and transversalis muscles could barely be distinguished, and even the tendon of the external oblique was scarcely to be distinguished; the sac contained a large knuckle of intestine distended with its contents, and lying below and to the outside of the intestine was the testicle in a healthy state; between that time and the time of the patient's death it had inflamed and increased somewhat in size.

Another material point in guiding the judgment of the practitioner in deciding as to the occurrence or otherwise of sphacelus was (Dr. McDonnell said) a fact observed here, viz., the very fetid odour exhaled by the liquid contained in the hernial sac. The surface of the intestine was tolerably smooth, but of a mottled greenish-yellow colour. The stricture was found at the internal ring, and the finger-nail was with some difficulty insinuated for the purpose of dividing it. Dr. McDonnell, having freely divided the stricture, left the intestine *in situ* for the time. He returned after a few hours. There was an apparent improvement in the patient's condition; but, as the intestine was still distended, he opened it freely, giving exit merely to the contents of the knuckle of intestine. During the two next days, no discharge of feces taking place, the patient was obviously sinking, and exhibited an aggravation of the symptoms. Dr. McDonnell now endeavoured to introduce a gum-elastic catheter and syringe, in the hope of finding the extremity of the intestine; but in vain. Acting, therefore, upon the rule, which he considers well founded, that the less such cases are interfered with the better, until driven to operation by the progress of mischief, he declined interfering further. At the end of the second day he again divided a stricture, and was strongly under the impression that the division took place at the same point as previously, that is, at the internal ring. After dividing this stricture, in introducing the finger in search of the upper end of the intestine (and here again was one of the interesting points of the case), this portion of intestine was torn from its adhesion to the inner aspect of the internal ring—a fact which, even had the case been otherwise favourable, would have produced a fatal termination from extravasation into the abdominal cavity. From the stomach down to the seat of stricture the intestines lay in large folds enormously distended, while the lower portion was remarkably small and flaccid. There was little inflammation except from the stricture up to the stomach, and very little coagulable lymph effused.

DEEP-SEATED ABSCESS OF THE NECK—CEDEMA GLOTTIDIS.

Dr. McDowel brought forward a specimen of a disease which, although it had already more than once been brought before their notice, yet was, as he judged it, one of such extreme importance, owing to its rapid progress, insidious mode of access, and too frequently fatal termination, that every fact relative to it should be laid before the profession; and, as such a society as the Pathological afforded peculiar facilities for effecting this, he deemed it his duty to bring the following case before the meeting.

The specimen, he further observed, was one of that form of acute laryngeal disease which is characterized by infiltration, either with serum or more rarely with pus, of the submucous tissue of the glottis, hence termed "cedema glottidis," or, by some writers, "laryngitis oedematosa."

The subject of the case from which the preparation was obtained was a man of the name of Patrick Kevin, aged forty-eight, who was admitted into the Hardwicke Hospital, under the care of Dr. McDowel, on the 7th inst. He was then labouring under pneumonia of the upper lobe of the left lung, travelling from above downwards, and accompanied by fever of an adynamic character. Under appropriate treatment the pulmonary inflammation was subdued, when the patient began to complain of pain below the angle of the jaw on the left side; here tumefaction and tenderness on pressure existed; in fact, deep-seated inflammation was set up in the cellular space between the fascia of the neck below the lower angle of the parotid gland. This, Dr. McDowel was disposed to regard as a critical abscess, such as is not unfrequently found selecting this locality in patients convalescent of febrile affections. For three or four days neither constitutional disturbance nor local distress was occasioned. However, on the morning of the 18th, the patient complained greatly of pain in the tumour; the motions of the jaw were a good deal restricted, and there was slight difficulty of swallowing observed; the integument over the swollen part was tense and unyielding, presenting a blush of redness on the surface and some oedema when pressed on. An incision was now made, and when the fascia was freely divided, healthy pus in considerable quantity was given exit to, and the patient expressed himself as being greatly relieved. On the evening of the same day, however, he complained of difficulty of breathing, even then very alarming, and which, although he had not mentioned it, had existed and been gradually getting worse for several hours previously. One of the clinical clerks then saw him, and found him breathing with the utmost difficulty—the inspirations being prolonged and loudly stridulous, and the difficulty of swallowing greatly increased; he sat up in bed gasping for breath—his face presenting a *lividly pale* appearance, and his skin bathed in clammy perspirations. Dr. McDowel was sent for, but before he could arrive the man died suddenly; stupor first, and afterwards two or three severe convulsions, preceding dissolution.

On examination, the abscess in the neck was found occupying the situation already indicated; it did not extend to the larynx, but the cellular tissue, between the base of the abscess and the exterior of the thyroid cartilage on the left side, was greatly condensed from solid effusion. On cutting into the larynx, considerable serous infiltration of its submucous tissue was observed; this engaged its upper opening, and on the left side chiefly. The aryteno-epiglottidean folds were so thickened as to overlap each other, and so, doubtless, acted mechanically in preventing the entrance into the lungs of atmospheric air. Having presented several drawings illustrative of the recent appearances observed in other cases of this affection, Dr. McDowel remarked, that had the abscess in the neck, from which the oedema of the glottis originated in the case he had just detailed, been neglected, and not opened sufficiently early, he would probably have felt reasons for self-reproach; but here,

after matter had been freely given exit to, and tension relieved, and at a period when usually no danger might be expected, this fatal complication occurred. A careful examination of the preparation, which shows how purely mechanical the cause of death here was, must, he observed, lead to the conclusion that nothing but an opening made into the larynx or trachea, lower down than the obstruction, could in such a case have afforded any chance of saving life—a chance which, in this case, was totally denied by the extreme rapidity of the disease.

Jan. 30.—Mr. HAMILTON in the Chair.

Dr. Banks said, the person from whose body the specimen he now presented was taken, was admitted to the Whitworth Hospital on the 21st of January, almost in a dying state. Her debility was so extreme that she was scarcely able to answer a question, so that hardly anything of the history of her case could be obtained from the woman herself. But the following facts were chiefly furnished by Dr. Denham, under whose care she had previously been at the Lying-in Hospital:—

The woman was forty years of age, married, and mother of eight children; she was a person of temperate habits, but of a highly strumous diathesis; her father and brother had both died of phthisis, and she herself had always been delicate. In the year 1836 she had an attack of acute rheumatism, for which she had been under the care of the late Dr. Crampton, at the Whitworth Hospital. In about six weeks she recovered from that illness, and enjoyed tolerably good health until October of 1846, at which time she aborted and lost an enormous quantity of blood, both before and after the abortion. She was at this period in the Rotunda Hospital, where she remained for some time, being in a very weak, debilitated condition, extremely emaciated, and suffering much from palpitation of the heart and pains in the lumbar region. In 1846 she again became pregnant, and was again admitted to the Rotunda Hospital. On the 27th of November, being then in the fifth month of pregnancy, Dr. Denham there observed that her countenance was pale and anxious, and her general appearance indicated extreme debility; three weeks before, she had a severe attack of uterine hemorrhage. She complained much of palpitation of the heart; no morbid sound, however, was heard. She suffered from sleeplessness, which was attributed to the palpitation.

The hemorrhage returned from time to time, accompanied with uterine pains, until the 7th of December, when she again aborted. From this period there was no return of the hemorrhage, but excessive prostration of strength and palpitation continued. On the 25th of December she left the hospital, contrary to the advice of Drs. Johnson and Denham.

On admission to the Whitworth Hospital, on the 21st of January, she was universally anasarctous, but particularly the lower extremities, and there was effusion into the abdomen. The skin of the face and, indeed, that of the whole body was perfectly bloodless. The lips, tongue, and lining membrane of the mouth, were blanched; the pulse was small and frequent, and the prostration of strength was so great that she was unable to move; the heart's action was feeble and labouring, but no morbid sound existed; the liver was felt below the margin of the ribs, and was tender on pressure; the bowels had not been moved for five days before. The posterior part of the chest was dull on percussion, with sonorous and sibilous râles all over it. She complained of extreme difficulty of breathing. The urine was found on examination to be of low density, a 1010, with slight traces of albumen. Bowels acted upon by enemata. Ether, brandy, and wine were administered. She died on the fourth day after admission.

On examining the body in eight hours after death, a considerable quantity of serum was found in the cavity of the abdomen, as also in the pleural cavity and the pericardium; the

heart was healthy, but rather more fatty than usual. The lungs were in an œdematous state when cut into, giving exit to a large quantity of frothy serum: this condition was most observable at the base. At one portion the lung, for about the size of an egg, was perfectly solid, the solid part being surrounded by healthy lung. The liver was enlarged and easily broken down; spleen large and soft. The kidneys also were enlarged and brittle; one of them particularly so, probably resulting from commencing Bright's disease. The uterus was found more vascular than natural, and a small fibrous tumour adhered to its posterior wall. The spermatic veins were observed to be coated with lymph, and the cava was also thickly coated with it, constituting phlebitis, the disease being found to have stopped short exactly at the junction of the cava with the right auricle. The whole lining membrane of the venous system, in fact from the heart downwards, was either coated with lymph or filled with coagulated blood. The pulmonary veins presented a similar appearance, as did also the deep epigastric vein. Considerable effusion had taken place into the tissue surrounding the femoral vein, giving rise to a fat resembling brawn.

Dr. Banks thought the case worth bringing under the notice of the society, so few instances are met with of phlebitis occupying so great an extent of the venous system. It was an example, too, of pure adhesive phlebitis, not passing into the suppurative stage. In no part of the body was there any trace of purulent deposit, the lungs, liver, and other organs having been accurately, but ineffectually, searched for it. The joints were also entirely free from such deposit. The axillary veins contained coagulated blood, but the veins of the arms were in the natural condition. The heart was quite free from disease, as was also the superior vena cava—the disease, as before observed, having stopped short at the point of junction of the inferior cava and right auricle. The history of the case, it is to be observed, from the period of her leaving the Rotunda Hospital, on the 25th of December, up to the time of admission to the Whitworth, remains untold, owing to the extremely debilitated condition of the woman when she came under Dr. Banks's observation.

Mr. Hamilton exhibited a diseased elbow-joint, and observed that ulceration of the cartilages of joints is generally found to follow either upon disease commencing in the bones or synovial membrane, and finally extending to the cartilages, or upon diseases primarily affecting the cartilages themselves. In the preparation now on the table, however, the disease had not originated in either of these ways; but commenced by an abscess external to the joint, which worked its way under the muscles and fascia of the forearm, and finally effected an entrance into the joint, where it gave rise to inflammation and subsequent ulceration of the cartilages. The present case Mr. Hamilton was disposed to feel the more interested in because of its being the second of that kind which had come under his observation within the last few months.

The first was a woman with lupoid inflammation at the outside of the knee-joint—an extremely dangerous locality, there being not more probably than the thickness of paper between the interior of the joint and the destructive external ulcer. In spite of the most careful treatment, the ulcer continued to deepen till the joint was perforated, followed by great swelling; profuse discharge of thin matter; pain, most violent and aggravated by spasmodic starts; and finally, the destruction of the ligamentous connection of the joints was such that dislocation of the tibia took place behind the condyles of the femur, with the limb in nearly a straight position. Three weeks after the joint had been perforated she died, amputation not being feasible on account of the presence of disease in the lungs. The cartilage had been ulcerated away from the articular surface of the femur to a great extent, leaving the cancellated structure of the bone exposed; also from the head of the tibia and

patella. The synovial membrane was dark green, and quite changed in appearance; the crucial and lateral ligaments destroyed, and scarcely a feature of the former state of the joint remaining.

The present case was as follows:—A man, aged about fifty-five or fifty-six, came to Mr. Hamilton about a year and a half ago, with a rather large chronic abscess in the middle of the front of the forearm, upon a free incision of which a quantity of whey-like and curdy matter escaped. After some time the opening had nearly healed, a small fistulous opening alone remaining, through which whey-like matter was occasionally discharged. About a month ago the swelling of the forearm became very great, extending to the elbow-joint, with loss of motion in the joint, severe pains, startings at night, hectic fever, and loss of flesh. It became evident that amputation afforded the only prospect of relief, and a few days ago, the patient having been previously placed under the influence of ether, the arm was removed.

On examining the forearm and elbow-joint, a fistulous track could be discovered from the seat of the abscess up the forearm, deep under the muscles, till it penetrated the cavity of the joint. As in the case of the woman who had the perforating ulcer of the knee, the cartilages were found ulcerated away from the greater part of the surfaces of the inner condyle of the humerus, and the corresponding portion of the inside of olecranon, the bone exposed and softened. The synovial membrane was red, thickened, and pulpy, the joint contained grumous matter, and several abscesses surrounded it.

PATHOLOGICAL SOCIETY OF LONDON.

NECROSIS OF THE SHAFT OF THE HUMERUS, AND OF THE HEAD OF THE FEMUR.

By Dr. Ogier Ward.

The patient, a girl aged ten, came under the care of Dr. Ward, in August, 1844, complaining of a tingling pain down the right arm to the hand, and of a right hip, down the back of the leg to the foot. This was followed, in six days, by a high state of fever and phlegmonous erysipelas of the right shoulder and arm. A large abscess formed in two days, and which was punctured about the middle of the arm, a large quantity of healthy and sanious pus escaping. A few days after the opening of the abscess, a red spot appeared over the head of the humerus, and which ulcerated in about a fortnight, and through the ulcerated opening, the head of the bone, deprived of its epiphysis, protruded to the extent of two inches, the other wound having healed in the interim. She soon afterwards entered St. Bartholomew's Hospital, where she remained fifteen weeks, at the end of which time nearly the whole length of the humerus was extracted, and the wound healed rapidly. After her return, there appeared to be ankylosis of the joint; and shortly afterwards she was thrown down, the new bone becoming bent at its upper third, in which state it still remains. At this time, the head and upper part of the thigh-bone were affected with periostitis, followed by the formation of several abscesses about the great trochanter, and the discharge, at intervals, of small pieces of bone. The disease of the thigh-bone continued for more than a year and a half, and the healing of the sinuses was immediately preceded by the coming away of a large portion of the head of the bone. The patient now enjoys good health, the right arm being shorter by two inches than the left; there is great mobility of the scapula, and when this fixed, there is motion of the arm to the extent of 20°. The right leg is an inch and a half shorter than the left; and in consequence of a false joint between the femur and ileum, she possesses tolerably free movement.

KIDNEYS OF AN INFANT PRESENTING CARCINOMATOUS DEGENERATION.

By Mr. Obro.

The subject of this case was the only child of

young parents, born apparently healthy, and continued so until its seventh month, when scrotal hernia presented on the right side. The following month, a hard abdominal swelling, the size of an egg, was felt in the anterior part of the left lumbar region, which rapidly increased, in a few days attaining the size of a small melon. No definite opinion being given of its character, he was visited by Sir James Clarke, who also was unable to decide either on its structure, or from what organ it had its origin, all the functions and secretions being apparently undisturbed. The rapidity of its growth suggested malignant disease; but that was the only symptom which indicated such a result. A fulness was shortly observed in the right hypochondriac, caused by a similar tumour under the hepatic region. In the course of three or four months, the swellings had gradually increased until they attained a most enormous size, filling the abdomen, pressing back into the lumbar regions, and so distending the abdominal parietes, that they required the application of oil to promote their relaxation from the enormous pressure within; the tumours coalesced till they presented no, definite boundaries; the distention was too great to prevent the child being placed in any position except lying on its face. It lingered in this state until its thirteenth month, when it died exhausted, emaciated to a miserable skeleton, presenting a sad object with this enormous abdomen. Occasional constipation and vomiting were the only distressing symptoms. The abdomen was the only cavity examined after death: its contents were pale and attenuated; the intestines displaced by two large, globular swellings, filling either side of this cavity, which proved to be the kidneys converted into cancerous structure, the right weighing two pounds twelve ounces, the left, two pounds four ounces; conjointly, therefore, five pounds. Their external surface is smooth, the fibrous covering not being diseased; internally, they are of an encephaloid structure, the several tissues of the organs being transformed into brain-like substance, but of firmer consistence; they had lost all character by which it could be supposed that they had been transformed from kidneys, not even the pelvis or infundibule being distinguishable; the left is lobulated as in the fetal state, having somewhat its normal form; the other has lost all anatomical character. These organs were not suspected to be diseased; therefore the urine was not chemically examined. After death, the bladder contained a little of this secretion, but only sufficient to detect its constituents, being largely impregnated with alkaline matter.

OSSEOUS TUMOUR REMOVED FROM THE FACE OF A GIRL, AGED FOURTEEN, INVOLVING THE RIGHT SUPERIOR MAXILLA AND THE MALAR BONE.

By Mr. Ferguson.

Enlargement was noticed six or seven years before the operation, and seemingly commenced in the alveolar ridge. There was no trace of the antrum. Patient made a favourable recovery, and has remained well since.

OSTEO-SARCOMATOUS TUMOUR FROM THE FACE OF A WOMAN, AGED 36, INVOLVING THE GREATER PART OF THE LEFT SUPERIOR MAXILLA.

The tumour projected slightly into the mouth, and filled the interior of the antrum. Portions of the alveoli had been removed on two occasions previous to the last operation, when the whole mass, including the malar bone, was extirpated. The operation was performed about three months ago, and there has been no indication of return of the disease. The reappearance of the disease, which does not indicate malignancy in its physical characters, may probably admit of explanation, by reference to the manner in which the growth has extended in an upward direction, so that it was not isolated by the horizontal sections of the alveoli which had been made for its removal at the first operation.

PORTION OF A MEDULLARY TUMOUR OCCUPYING THE SITE OF THE SUPERIOR MAXILLA, REMOVED, AFTER DEATH, FROM A MAN, AGED FIFTY-FOUR.

An operation had been proposed at an early

period; but the patient refused to submit. The tumour grew rapidly, and he was anxious for an operation when it was too late. It extended to the base of the cranium, and had all the characters of malignancy.

TUMOUR OF THE LOWER JAW, removed by Mr. Key. The patient, a boy, aged thirteen, was admitted into Guy's Hospital in October, 1841. He was pale and sallow, with a high and somewhat projecting forehead, light hair and eyes, and emaciated appearance. In consequence of his not being able to articulate distinctly, some difficulty was experienced in obtaining a history of the case. The following particulars were noted at the time:—

About two years ago, a small lump appeared on the anterior part of the lower jaw, gradually increasing and extending backwards, forcing out, after a time, many of the lower teeth. Has never experienced any pain. The jaw gradually increased in size, when he applied to a surgeon, who tried various remedies without relief. Has always enjoyed a fair share of health, and can eat and drink well.

When admitted into the hospital, the lower jaw was apparently much enlarged and thickened, and advanced beyond the upper, having, resting upon the upper part of the symphysis a globular, vascular sarcoma, which, about fourteen days back, had begun to ulcerate on the surface, and at intervals bled profusely. Styptics were applied to arrest hemorrhage.

Seven days after admission, Mr. Key determined to remove the diseased part, which was accomplished in the following manner:—An incision was made along either side of the horizontal ramus of lower jaw, commencing from the angle in the hollow of the neck, meeting each other in the mesial line; the flap was turned up, and the cut vessels immediately secured; the lower jaw was sawn through, just anterior to its angles, detaching a small portion of the masseter muscle on each side. The jaw was carefully dissected out, the flap brought together, and sutures applied.

On the fourth day the sutures were removed, and the whole of the wound had nearly healed. He left the hospital on the 9th of November, having had no bad symptom, and is now in perfect health.

Dr. Hall Davis exhibited

MICROSCOPICAL PREPARATIONS OF MOLLITIS OSSEUM,

with which a woman, dying from rare uterine disease, the particulars of which had been submitted to the consideration of the society some weeks back, had been affected. Dr. Davis had previously submitted some specimens to the examination of Dr. Sharpey, Mr. Dalrymple, and Mr. John Quckett, who had remarked that the Haversian canals were much larger than natural, as also the bone cells; and in parts, near the edges of the bone, forming the wall of the Haversian canals, the canaliculi were but slightly visible, or had entirely disappeared. The bone along the edges above mentioned was extremely transparent; and numerous nucleated cells, blood discs, and fatty matter, occupied the cancellated structure, and some of the Haversian canals. The bone had also been examined chemically by Dr. Garrod, who found that 100 parts dried at 122° yielded—

Phosphate of lime	16.40
Carbonate of lime, with phosphate of	
magnesia	4.88
Fatty matter	20.35
Gelatine yielding matter	58.37

100.00

thus exhibiting a considerable difference from the proportions given for healthy bone by Berzelius—viz.,

Earthly matters	66.70
Animal matters	33.30

The history of the case was then detailed, and it appeared that the female had, at the commencement of the affection, lived in a dry climate, and for the last six years of her life in Lancashire, on the borders of a lake surrounded

by woodland. There had been no hereditary tendency, the father and mother being still alive, as also five other children, all enjoying perfect health. She had never been affected with rheumatism, and died from an acute attack of pneumonia.

ANEURISM BY ANASTOMOSIS, IN THE SUBSTANCE OF THE PARIETAL BONES.

By Mr. Toynbee.

The subject of the disease was a youth aged nineteen, who died of consumption. He was brought into the room for dissection; and there is no evidence to show that the disease was detected during life. Corresponding with each parietal eminence, there is a rough and slightly elevated portion of bone apparently occupying the centres of ossification, and situated about an inch from the coronal, and an inch and a quarter from the sagittal suture. These osseous projections are pear-shaped, the apices being directed posteriorly, and the broad ends in front. That on the right side is rather the larger, measuring three inches in length, and at its greatest breadth one inch and three quarters; that on the left side is in length two inches and three quarters, while its breadth is an inch and a half. The surface on the right side measures seven inches in circumference; that on the left, seven and three quarters. The right projection, though as broad as its widest end, diminishes so much as to be not more than three quarters of an inch at its narrowest. On further examination of these surfaces of bone, they are found to present at their circumference a certain degree of unevenness, caused by numerous superficial grooves, as if from vessels lying upon the bone. These grooves radiate from the circumference of the surface; and as they approach the portion of bone most diseased, they become deeper, and small orifices are observed opening into them. The rough surface itself is composed, firstly, of grooves, which are in some parts from a line to a line and a quarter in depth; secondly, of osseous cavities, about a line in diameter, and bounded laterally by the walls of the canals; thirdly, of canals which admit of a free communication between the grooves. These grooves, cells, and canals, are so numerous, and their intercommunication so intricate, that they form a labyrinthine network of singularly beautiful appearance. Into the floor of the canals and sulci innumerable orifices enter. The grooves and canals were, in the recent state, full of an intricate network of ramifying bloodvessels, but it was impossible to inject them, from their being cut into before their nature was detected.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Feb. 23.—Dr. COPLAND, F.R.S., in the Chair.

CASE OF ELEPHANTIASIS.

By George Southam, Surgeon to the Safford Royal Hospital and Dispensary, Manchester.

(Communicated by Mr. T. B. Curling.)

The patient, an unmarried female, first came under the author's notice in the autumn of 1843. The disease had then existed about twenty years, and commenced when she was in her eighteenth year, on the dorsum of the foot, having been preceded by attacks of deep-seated pain. As the oedema extended, the pain became more severe, and the integuments became the seat of frequent erysipelatous attacks. A large ulcer formed on the inside of the thigh, and three others near the ankle. The only cause assigned for the disease was the sudden cessation of the catamenia from cold. A drawing of the disease, taken in 1845, was exhibited to the society; the measurement round the calf of the leg was two feet nine inches; above the knee, three feet four inches; and at the upper part of the thigh, including the nates, five feet six inches. Owing to the integuments having yielded unequally, the leg had a somewhat lobulated form; there was neither indentation nor pain on pressure; the sole of the foot was the only part of the limb

not implicated. She was able to go about the house, and assist in household duties, until within a few weeks of her death, which took place on the 21st of November last, from an attack of dysentery.

On examining the body, the enlargement was found to have been caused by the deposit of a dense, white, lardaceous substance, interspersed with fat, in the subcutaneous cellular tissue. The principal venous trunks were much larger than natural, and when divided transversely, were patulous. The coats were thickened and converted into a fibrous substance, disposed round the vessel in laminae. All the smaller vessels, when divided transversely, resembled arteries filled with coagula. The disease in the veins had not extended beyond the groin; those of the pelvic cavity were sound; the viscera were healthy; nothing beyond slight hypertrophy of the epidermis and cutis was detected in the skin.

The author remarks, that he has been informed by several medical friends who saw the patient, and who had witnessed elephantiasis as it is met with in the natives of South America and the West India islands, that the tumefaction seldom attains so great a size as was observed in the case now related. From the appearances found on dissection, it is evident that the disease originated from repeated attacks of subacute or chronic inflammation of the venous capillaries, which caused the pain and febrile symptoms. The author is of opinion, that the immediate cause and pathological changes of elephantiasis bear an intimate relation to those of phlegmasia dolens and the induration of the cellular tissue, in newborn children; the apparent differences depending on the degree of venous obstruction, and on the remote influences which have originated it.

Mr. Curling mentioned a case in point, recorded by M. Chevalier in the second volume of the Society's "Transactions."

ON TUBERCULAR PERICARDITIS, WITH PATHOLOGICAL AND PRACTICAL REMARKS.

By George Burrows, M.D.

After alluding to the rapid advances made in our knowledge of diseases of the heart during the past twenty years, the author refers to the paper of Dr. Taylor, "On the Causes of Pericarditis," published in the twenty-eighth volume of the Society's "Transactions," where that physician assigns rheumatism, granular disease of the kidneys, and extension of inflammation from contiguous parts, as the chief causes of pericarditis. To this opinion the author assents, but invites the attention of the society to another form of that disease, which he designates tubercular pericarditis. After taking a review of the statements of different pathologists who have described tubercular deposits in the pericardium, more especially of the descriptions of Baillie, Laennec, Andral, Louis, and Rokitsansky, and of the opinion expressed by the latter, that tubercular diseases of the pericardium are the consequence, and not the cause, of chronic inflammation of that membrane, the author proceeds to detail three cases of tubercular pericarditis.

CASE 1.—A young Italian was admitted into St. Bartholomew's Hospital, labouring under the symptoms of incipient phthisis. After three weeks' residence in the hospital, the appearance of blood in the sputa caused a careful examination of the chest by the stethoscope to be made, when the physical signs of unsuspected pericarditis were detected. The friction-sounds of pericarditis were heard through fifteen consecutive days, and then subsided, leaving no cardiac murmur. At the expiration of two months, a fresh accession of fever, and examination by auscultation, indicated the presence of double pleurisy, which continued during nineteen days, when the man died. The post-mortem examination revealed the existence of abundance of effused lymph in the pericardium, of copious serous and fibrinous exudations in the pleura as well as in the peritoneum. Numerous opaque, yellowish tubercles were found disseminated throughout the self-coagulable lymph effused on these membranes. The

lungs also contained numerous tubercles in the crude state scattered throughout the different lobes; the bronchial glands and spleen also contained tubercles.

CASE 2.—A young man in Millbank Prison, when convalescent from chronic dysentery, was attacked with the symptoms of incipient phthisis, but auscultation detected no signs of extensive tubercular disease. The young man sunk, and, upon examination after death, both lungs were found thickly studded with yellow tubercles, varying in size from a millet-seed to a small pea. The pericardium contained a large quantity of firm lymph, intensely stained with blood; and upon separating the layers of lymph towards the base of the heart, several small yellow tubercles were distinctly recognised in those portions which were most carefully examined. A coloured drawing of this heart was exhibited to the society.

CASE 3.—A young man, who had been imprisoned in the hulks and at Millbank, became the subject of dysentery in the latter prison, from which he was convalescent, when he exhibited the symptoms of phthisis. Upon auscultation, Dr. Baly detected the presence of pericarditis, and he was forthwith removed to St. Bartholomew's Hospital. The physical signs of pericarditis were manifest during twenty consecutive days, and then disappeared, leaving the heart exempt from all murmurs. This young man quitted the hospital, convalescent, a few days after the cessation of the pericarditis; and, although his recovery prevented the verification of the diagnosis of pericarditis, still the history of the case, so closely analogous to that of Case 2, and the absence of the usual causes of pericarditis, induced the author to regard Case 3 as one of tubercular disease of that membrane. The author then points out the class of cases in which this rare affection may be suspected—viz., in those persons who, having been long exposed to the most powerful exciting causes of tubercular cachexia, exhibit symptoms of incipient phthisis; and yet the auscultatory signs of tubercles in the lungs are inconclusive. In such persons tubercular affections of serous membranes and of the pericardium should be looked for. The author then considers the pathological question, whether the tubercles are to be regarded as the cause or the effect of these chronic inflammations of the pericardium. After quoting the opinions of Laennec and Rokitsansky, who appear to regard the tubercles as the result of a change taking place in the layers of fibrine, consequent upon acute inflammation, and which tubercles then cause the inflammation to become chronic, the author endeavours to show that it is more in accordance with our present knowledge of the history of tubercle, to suppose the tubercles to be deposited on the pericardium in the first instance; and that these foreign bodies, acting as exciting causes of inflammation there as elsewhere, keep up chronic inflammation. A similar train of phenomena may be observed in chronic tubercular peritonitis. The author concludes by pointing out how inapplicable the usual remedies for pericarditis are in the tubercular variety. Large losses of blood and the lavish use of mercury should be abstained from; while counter-irritation over the chest, saline diuretics, with combinations of iodine, and the speedy removal of the patient from the influence of depressing causes, are the means most likely to arrest the progress of chronic pericarditis produced by the irritation of tubercular deposits.

REVIEWS.

Facts which Prove the Immediate Necessity for a Measure of Sanitary Reform. By JOHN CHARLES HALL, M.D., &c. 8vo., pp. 60. London: Longman and Co., 1847.

Dr. J. C. Hall is well known to the profession for several able communications on subjects connected with medicine and surgery. His writings, are for the most part of a practical character and are, therefore entitled to our best considera-

tion. Years of experience and careful observation must necessarily have qualified him for judging correctly upon subjects connected with the sanitary condition of the public at large; and we are, consequently, right glad to find that his energies are being devoted to a conscientious investigation into the subject of the health of towns. It is a topic pregnant with importance, and we earnestly hope that others of our profession, who may have fitting opportunities for a like investigation, will prosecute it in due faithfulness. This topic has much to be said upon it, as our author eloquently observes:—

"With all our boasted knowledge, the star of civilization is still clouded, and the art of government is in its cradle; and yet the womb of the future is pregnant with much that is good; public attention has been, and is still about to be more closely than ever, directed to the sources of fever—to the means by which the filth of our cities and villages may be removed, and the frightful ravages of syphilis controlled. Then, and then only, may we hope that the value of life will be increased, and increased it most assuredly must be, by the removal of these heaps of filth—these noisome open drains—the whole paraphernalia of pestilence which is daily exhibited around the dwellings of the poor; and lastly, by the removal of all places of internment beyond the walls of towns."

The observations of Dr. Hall upon this most important subject (would that every practitioner would view it in the same light, and as honestly and ably treat it!) were suggested by several cases of fever, which he was led directly to account for by reference to the particular circumstances, atmospheric and other, in which the sufferers were placed. He says:—

"We have been led to make the above remarks from the unusually large number of cases of gastric fever which have come under our own care, or the care of some of our professional friends; and, from our own experience, we venture to state that the great majority of the cases of fever we have seen, during a somewhat extensive practice, both in London and the country, may be traced to a neglect of the proper sanitary measures for clearing away those nuisances, which are the prolific nurseries of pestilence, and the parents of death. Near one of the houses in which the first case of fever broke out, is an open drain, into which several soughs, carrying offensive and putrid matters, arising from animal and vegetable bodies in a state of decay, ran. So offensive were the effluvia arising from it, that we called once or twice at the door of the house and cautioned the occupier of the danger he and his family exposed themselves to. No notice was taken by the good easy man. To his house we were first called to see his son, a youth of nineteen; this case was a very severe one; he recovered. A young girl, his sister, was next attacked slightly; the mother was the next victim; she died. Another child, aged five, was then attacked most severely, and recovered; this child altogether lost the power of speech for some weeks, and even now it has not perfectly returned to him. Crossing the road, in another house, a young woman was attacked with the same fever, and died; and, in the same house, we afterwards attended a little boy and an old man, who both suffered most severely; and another case occurred within twenty yards of it. Going down a narrow lane, about 120 yards in a direct line from the house first mentioned, we attended an old man and his wife, both suffering from the same fever; and fifty yards along the same lane, in a house surrounded by heaps of filth, another case of the same fever came under our care." (Pp. 5 and 6.)

These are startling, serious truths, told with no wavering or want of purpose. Of such truths, boldly related, and with the best intention, is Dr. Hall's work made up. We wish we had space further to quote his valuable remarks. They do infinite credit to him, both as a philanthropist and a physician, and we warmly commend his able monograph both to the profession and the public.

TO CORRESPONDENTS.

THE MEDICAL TIMES may be procured by an order on any Newsmen or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angersstein Carfrae, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 13s.; Quarterly, 6s. 6d.

A HANDSOME PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 6s. An allowance is made to the trade.

We beg to direct our readers' attention to the magnificent work on *Physics*, which is commenced in the *Pharmaceutical Times*. It will be illustrated by 600 beautiful engravings, and continued weekly without interruption to its conclusion, which will be reached in about 35 numbers. The annual joint subscription to the two journals (*The Medical Times* and the *Pharmaceutical Times*), is two pounds.)

F. A.—There is no chance of any bill passing this session. In England the body that has the repute of giving diplomas on the cheapest terms, as far as qualification goes, is the Royal College of Surgeons of England. We are, however, unable to say if they are contented with less than any other corporation in Great Britain and Ireland. When there were no fellowships the members had to undergo a respectable examination. It is now, we believe, otherwise.

Y's inquiries about the injustice he has suffered from his coroner are answered by Lord Denman's celebrated judgment—the judgment, indeed, of the whole Court of Queen's Bench. The Hounslow inquest having developed every kind of hardship to which a medical man can be exposed under all circumstances of inquest-mismanagement, Lord Denman's judgment meets every injustice of which our correspondent complains.

"A Subscriber and Well-wisher," on the same subject, shall be published next week, with some remarks by ourselves.

A. F. G. R.—The rapid absorption and fatality of prussic acid applied externally, forms one of the unsolved problems of medicine.

A mass of correspondence must lie over till our next number.

We receive so many cases of letheonic operations, which would be of no public service to publish, that we must again remind our correspondents that in every case sent us, there should be some new or interesting point evolved to justify its publication.

Mr. Hardwick's letter has been received.

M. R. C. S.—The question put to us can be answered only by the Secretary, or one of the Officers of St. Andrew's.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the progress of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the path of disease, the effluence of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract love of a pedantic and insupportable lore. Every power of his mind is engaged; he is forced by the sympathies of his nature to

hear and see, to observe, to reason, to prognosticate, to be experimenting; each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diploma or license.

8 of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is *bona fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, MARCH 13, 1847.

"Respice quid moneant leges, quid Curia mandet;
Præmia quanta bonos moneant."

JUNIAL.

We will stoutly maintain that English civilization will have attained neither its true development nor stability, until the position of medical men, in reference both to the Government and to society, undergoes a total revolution. Their mission is not understood: their faculties not taken account of: their capabilities utterly misappreciated. They are no longer a body of men whose responsibilities commence with disease and conclude with death—and who, when in best exercise, are but "conductors of drugs, of which they know little, into bodies of which they know less." Time, that has stripped other professions of their utilities and influence, has endowed ours with more than the difference. While it is the boast of RELIGION, that she is no better now than when eighteen centuries since she first appeared to humanize and bless a depraved and animalized population,—while LAW remains, as ever, a social curse scarcely less grievous than the curses it would ward from us, and whose uselessness for good is best evidenced by the hourly-increasing call for its calamitous exercise,—MEDICINE has walked its onward march through centuries, with tortoise pace but sure, every step an increase of knowledge, and in every increase of knowledge the germ of nations on nations' happiness. We have been for the world the advance guard of intellect. We have made the only true knowledge—the knowledge of that physical advancement must depend—science. We have never stood still. In the dark ages we added the works of Avicenna and Geber to those of a Hippocrates and a Galen, and, even then, groping in a world of almost Cimmerian obscurity, evolved that cause and mainstay of modern civilization—chemistry. We have disarmed circumnavigations of their terrors and perils; evidencing, under Cook, that vessels of war may voyage round the globe and not lose a man. Lethal factories we have made healthy; deadly colonies compatible with European life; towns scarcely less unfavourable to health than the country; diseases mitigated, others enfeebled, some ex-

tinguished. Whatever, in truth, the intellectual and moral superiority of the present generation, it is our work and our merit. We were the first to evoke it, and are now the first to turn it to profit and public utility.

The State comprehends neither the *much* that we have done nor the *more* which we ought to do, and can do. It knows not that, while law and religion have been contracting their utility, we have been expanding ours. The religious teacher has not only abandoned law and physic, but so wholly gives himself to speculative theology that even morality is left by him, in nine cases out of ten, as a specialty for some other authority. LAW is so busy between individuals that the rights of the public are forgotten. Their abandoned functions we take up, and aid them in those they retain. To the well-meaning we recommend virtue by showing its physical rewards: to their adversaries we enforce moderation by making sure the detection of vice: we are, in some sense, the substitute of conscience in an age where the control of religion appears on the decline.

Our utilities, indeed, have no measure save the boundaries of science and the requisitions of humanity. We are allied to every part of the population—tied to them alike in their pleasures and their sufferings; influencing, by our knowledge, now the legal regulation of their property; now the aspersions or clearances of their suspected characters; now their legal innocence or guilt; now the healthiness of their locality—of their employments—and their houses; in short, personally, domestically, legally, socially, we are the exponents and authorities of what is true, and what is right. With the smallest rewards we have the heaviest responsibilities; with the highest state utilities we have the worst possible state position. In short, our duties and dues, our powers and possessions, make us the great social anomaly of our time.

It is a cardinal part of our duty personally, and of the policy of the whole profession, to keep this discrepancy fully in the public view. It is right that the Government should be hourly admonished that they are playing false to the substantial and best interests of those whose wellbeing they should watch over, in tolerating the existence of such a chasm—first, between the profession and its full development; and, secondly, between the profession and its full appreciation. There should be a league of intellect and science to extort justice from the public. There could be no greater benefaction even to the public. Every instance of Government liberality in that novel direction should be welcomed—should be encouraged. Every instance of Government meanness in that direction should be just as energetically marked and reprobated. The Chemist Marsh dedicated his life to the service of the Government, winning by his discoveries a European name. Ill paid through life, he died and left a widow in penury. The Government, then—that of Lord John Russell—that marked their sense of these high services, and the touching appeal made to them by the widow, by a cheque for twenty guineas, ought not to go unscathed. It should be a stigma on their management

never to be forgotten by the man of science, so that future historians chronicling the meanness may have the satisfaction of feeling that their judgment has not been unanticipated even in our own days. Again, the Government of Peel in a somewhat different spirit, originated more than one scientific commission and winning useful services treated the donors—whether an Owen, a Lindley, a Kane, or a Playfair—with liberality, with justice. We well remember the miserable acerbity with which some public writers—men of literature too!—delivered themselves on that occasion. The Minister was charged with silly extravagance, the men of science as overpaid and too well used. Prudence and the plainest justice require a very different course. Whatever the feuds that divide men of science, they should never be indulged in at the expense of the whole craft—and at the result which that supposes—the retardation of improvement. Let us unite to hail every step which recognises the claims of knowledge and the prerogatives of mind. To fail is a self-betrayal. It is not long since that a celebrated member of the French Institute, M. Double, was refused a peerage, which on many accounts was acknowledged to be his due, on no better ground than that he was a medical man. Our astonishment that such prejudices should be felt in France—and at Paris too—is perhaps as great a compliment to French public opinion on this subject, as our tame acquiescence here, to such scientific insults infer a reproach to ourselves.

However heavy the personal grounds, we have to press this social charge on the Government, they are but as dust in the balance compared with the social improvements involved by the alteration. We are a large body, comparatively unemployed, while thousands of matters—the most important to the wealth, the health, the well-being of the community—in-vite, demand, require an attention we may not and cannot give them. How much does this imply?

DEPUTATION TO SIR GEORGE GREY.

We are authorized to state, that a deputation from the Council of the Provincial Medical and Surgical Association has had an interview with the Right Hon. Sir George Grey, and that, from the result of this interview, strong hopes are entertained that a settlement of the questions connected with Medical Reform, satisfactory to all branches of the profession, may be obtained. These hopes are, however, dependent upon some approach to unanimity, in the concession of minor points, being manifested by the different sections of the profession.

APPEAL TO THE MEDICAL PROFESSION THROUGHOUT THE KINGDOM, ON THE GENERAL MEDICAL ANNUITY FUND.

GENTLEMEN,—The project for establishing a General Medical Annuity Fund for disabled members of the profession, and for widows and orphans, has now been nearly two years before the public. It is true that in the first instance it was designed to form an integral part of the affairs of the Provincial Medical and Surgical Association, but the meeting at Norwich having decided that it should stand alone, a separate and distinct institution from that body, it now becomes necessary to reorganize it, and give its independent existence that permanence and stability which its value and importance demand.

The unexpected decision of the Norwich meeting somewhat staggered me, for I had previously felt I was acting under the auspices of the Provincial Association, and that many members of that important body had not only lent their powerful names to the institution, but had aided its advancement by donations and subscriptions; still, though I was staggered, I was not paralysed in my energies, or disheartened as to the final accomplishment of the project, even though it stood alone: for that which possesses in itself an intrinsic virtue seldom requires foreign aid to sustain it. The human heart, although corrupted by selfishness and deadened by apathy, has many soft and gentle impulses which need but the right stimulus to excite into activity; and, when excited, a freshness and beauty is given to character—superior to renovated bodily vigour after the wastings of disease, for “true philanthropy is health of soul!”

Although the motives which have impelled me in all I have done in this matter are open to God, and I trust unimpeached by man, I have nevertheless felt a delicacy in obtruding myself—an unwillingness to seem too prominent—a desire that that which was of general interest to the profession should find amongst its ranks others who would step forward and bear with me the heat and the toil. I thought, if the project was worthy of support, the acknowledged talent of an enlightened profession like ours would be employed in its behalf, and expected ere this to have found many advocates: nor have I been altogether disappointed. To the Editor of this periodical I am indebted for valuable assistance in two leading articles devoted to the cause; and Mr. Kelson, of Sevenoaks, Kent, has furnished to the “Provincial Journal” a letter which evinces an enthusiasm worthy his benevolent spirit, and an activity, in a pecuniary point of view, which is an unequivocal earnest of his sincerity. If every county in the kingdom would produce a spirit like his, the prosperity of the institution could not be problematical. My thanks are likewise due to those gentlemen who honoured me with an answer to a circular published a few weeks back. They have with much kindness encouraged my efforts, expressed a confidence which is cheering, and, moreover, have promised active co-operation so soon as they shall be put into a position to become active. This latter promise is more congenial and satisfactory to my mind than all the compliments they have been good enough to pay to me, for I feel that counsel and help are essential. It is a gigantic establishment which is contemplated—a vast institution, comprehending in its grasp a huge tract of territory, and having for its object a diffusive spirit of benevolence. I, therefore, trust that many of these gentlemen will give to us their personal presence at the forthcoming meeting at Northampton. It is worth while in such a cause to make some sacrifice.

I am informed, both by the public press and by private letters, that the “General Medical Annuity Fund” has many well-wishers, who are at present unknown as its supporters. These gentlemen are in abeyance, waiting the further development of the scheme, and its final establishment, ere they give to it their countenance and support. To such I would remark—“If you think well of the scheme, why hesitate to support it? Your help is most needed now, in the early stages of its establishment, when your opinions and your counsel might lead to valuable results. The growth of a tree depends much upon the planting: if the labourers fail to loosen the earth, to arrange the fibres, to seek congenial soil and proper locality—if they neglect to watch and water it, to shelter from the rude blast, and sustain its delicate and yielding form from the rough winds which blow upon it, the chances are that it perishes. But if, on the contrary, they combine their powers, and unite their skill in all that be necessary for its sustenance, then shall it take deep root in the earth, rear its majestic form, thicken its bole, and spread around its branches, while its impervious foliage shall

shelter from heat and storm, and beneath which they may repose in calm security.”

To advance the interests of medical science is a duty we all owe both to the public and ourselves. To watch over the political movements which bear upon our profession—more particularly at a time like the present, so rife with such movements—is equally important; but let not the claims of philanthropy and benevolence be lost in the struggle. Let their still small voice be heard—they speak to the heart, and it should feel it. In this age of general improvement, when the spirit of amelioration is abroad, and societies are established to meet the contingencies of disease and death—the calamities which accompany such visitations,—when the artisan, the mechanic, nay, the agricultural labourer, have combined to furnish help to their distressed brother, and to the bereaved families of their departed fellow-workmen,—can it be endured that we who claim for ourselves the advantages of education, the privilege of expanded minds, the influence of moral and religious feelings, and in some measure the pride of clanship,—can it be endured that, in pure benevolence and nobleness of spirit, we should be outdone by these? Does the cause of the widow and the orphan require either eloquence or talent to plead with enlightened men? Is not the certainty of their fallen condition, when shrouded with poverty and neglect—oftentimes their utter helplessness, their agony, their privations—eloquence itself? Cannot imagination picture how forlorn and miserable must be that object who, having once enjoyed ease, comfort, and competency, is, from no fault of her own, but from the dispensations of Heaven, thrust from her home and her pleasures to toil for bread, to sink into dependence, or to have her weekly dole from the hands of a parish functionary? It is rank hypocrisy to put up a prayer to Almighty God in the venerable ritual of our Church, asking Him “to defend the fatherless children and widows,” while we refuse a small mite from our resources to make the prayer effectual, as far as human means can make it.

The difficulties under which many worthy and intelligent practitioners labour, in a pecuniary point of view, render assurance upon their lives often impossible; but, admit that a prudent and careful man has paid from his yearly income sufficient to guarantee to his widow a thousand pounds, now, what is the interest she will receive from this amount? Unless she adopts some speculative mode of investment (which is always dangerous), or, to obtain large interest, gets security—uncertain as to the punctuality of payment, her income from the ordinary funds of the country will scarcely afford a very humble maintenance for herself; but if she have a family it is obvious she must herself labour to obtain any respectable position, and it may be she is utterly unqualified for such labour. The capital must not be touched, for that capital is designed for ulterior purposes—to place her children in suitable situations, and to enable them in the end to embark in business on their own account. Now, to meet such cases is the great object and design of the directors of the “General Medical Annuity Fund.” An annuity accruing from such a co-operative institution would place the widow in a position of comparative independence. But when the average calculation of mortality amongst medical men, as proved by statistical returns, is compared with other professions, the lowest on the scale, the inference is fair that many die before they can have had time to make provision of any kind. Take the following fact as an example:—A young physician, respected for his general demeanour, and honoured for his talent, possessing public appointments, with every prospect of obtaining extensive practice, died after a short illness, “a few minutes only, at the early age of thirty-six, leaving a widow and five children totally unprovided for.” I quote this passage from an esteemed correspondent, to show that I have not drawn my picture from imagination, but trusted the detail of facts.

The proposition for a “General Medical Annuity Fund” has occupied the consideration of

wiser heads than mine. Dr. Percival, in his "Medical Ethics," more than forty years ago, threw out the suggestion, but no one appeared to act upon it. I have quoted the passage in former communications to medical periodicals, but it will bear reiteration:—"In the county of Norfolk and in the city of London, benevolent institutions have been lately formed for providing funds to relieve the widows and children of apothecaries, and occasionally also members of the profession, who become indigent. Such schemes merit the sanction and encouragement of every liberal physician and surgeon, and, were they extended, their usefulness would be greatly increased, and their permanency almost with certainty secured. Medical subscribers from every part of Great Britain should be admitted, if they offer satisfactory testimonials of their qualifications. One comprehensive establishment seems to be more eligible than many on a smaller scale: for it would be conducted with superior dignity, regularity, and efficiency; with fewer obstacles from interest, prejudice, or rivalry; with considerable saving, in the aggregate, of time, trouble, and expense; with more accuracy in the calculations relative to its funds, and consequently with the utmost practicable extension of its dividends." (a)

Some gentlemen have thought a guinea a year subscription would be inadequate to accomplish the object we design. It is scarcely necessary to enter again into this question, for I have met it on many occasions. A guinea a year subscription will enable us to fulfil the engagements to which we pledged ourselves (b), and, should the institution meet with the patronage it deserves, it will do much more, because the liberal and the kind-hearted of the profession will not confine themselves in their philanthropy. We have already had examples of this fact; nor will the public, when it is properly represented to them, withhold their assistance in furthering so exemplary an object.

If our anticipations in these particulars be realized, we may fairly hold out the prospect of better annuities.

It has been stated too, publicly, that there is an objection in sending money to Northampton, and that making application for annuities there would be inconvenient; but what is the consequence of locality to a "General Medical Annuity Fund," provided the parties who control it are men of integrity and honour, and provided the representative system be fully carried out? It will be our great aim to neutralize all objections of this nature. When the project was first mooted, it was done at the annual meeting of the Provincial Association, held at Sheffield; it was received there without a dissenting voice, and a committee for carrying out the scheme was appointed upon the spot. The retiring president of that Association, Dr. Robertson, of Northampton, kindly accepted the office of treasurer, while the directors were all gentlemen, chosen for their high standing in the profession, and their known integrity; for my own part, I took the office of honorary managing director, only as an earnest of my zeal, devoting to the cause my time, and the small measure of ability I might possess; being, in short, willing to "spend and be spent" in the noble undertaking. But the institution is now a citizen of the empire, and is ready to take up its abode where it has the best chance of support. I am willing, at any moment, to yield the feeble protection I have given it, to any more efficient guardianship; nor do I believe an objection would be raised by my colleagues, to placing it in a position of greater advantage than we may possess. Our object is the final establishment of the "fund," and we care not who are the parties who shall develop its energies and spread abroad its usefulness.

The medical profession throughout the kingdom are especially invited to the consideration of this subject. Honorary local secretaries are

appointed in the different counties, and districts, for furthering the scheme, and we shall esteem it an especial favour, if gentlemen will accept this office voluntarily—that is, will offer their services rather than wait for an application. Oh! let them remember the greatness of the cause, and the glory of its achievement, and methinks they will not lack in their zeal.

In the early part of the spring, a meeting of the subscribers will be held at Northampton; of which due notice will be given by advertisement in this journal. In these times of rapid travelling, when railway communication puts distance at defiance, we earnestly hope that many gentlemen will sacrifice to us their time and services on this interesting occasion. A noble superstructure is about to be raised, the foundations of which are love in its best and purest acceptation, while its hallowed cement is co-operative philanthropy, upon which the blessing of God shall rest, for God will not withhold His blessing when men "hear the cry of the orphan, and wipe tears from the widow's eyes."

Gentlemen who desire to be present at this meeting will confer a favour if they will apprise either Dr. Robertson or myself of their intention.

I have the honour to be, gentlemen,

Your obedient servant,

E. DANIELL, Managing Director.
Newport Pagnell, Bucks, March 1.

MR. CLOSE ON HOMŒOPATHY.

The following observations were written before the appearance of Dr. Orpen's letter in this day's *Medical Times*, and do not specially relate to the discussion now carried on by that gentleman and Dr. Hilbers, although they will be found to contain a reiteration of the challenge advanced by the former writer.

They were more immediately elicited by the passing fireside reminiscence of the Editor of this journal having promised his readers some reflections upon the subject. Whilst musing upon the probable causes of their non-appearance, "thinks I to myself," Homœopathy has had its day; like its hydropathic sister, it is on the wane: nevertheless, it has not stated and promulgated its hypotheses and dogmas, nor ruffled the surface of established medical doctrines, without producing some effect on men's minds. The agitation of any question is sure to attract attention; the attention excited will be in the ratio of its novelty; error for a time may be dominant, but, as time rolls on and sober thought acts, the chaff of error will be winnowed from the pure grain of truth, and "truth must prevail." I have watched the revivification, progress, and decline of the system with interest, as anxious to select its truth as to reject its error.

One correct impulse to legitimate medical science may be derived from the attempt to discover a universal law affecting the phases and treatment of disease. This cannot be heterodox or irrational. Experience and analogy tend to support it. But as, in other instances, the law ought to be sought for *inherently*, rather than *extrinsically*. Gravitation, electricity, magnetism, are general laws which coexist with, and depend upon, the integrant constitution of the natural objects themselves; so likewise the healing law, it may, *a priori*, be anticipated, should be sought for, and will be found, in the organic construction of the living being itself, and not in the extrinsic material which may be brought to act upon it. This law has been long recognised as the *vis medicatrix*, and not the *similia similibus*. To watch, to assist, to control its operations, make up the sum of the true philosophy of medicine. Acting, not upon matter merely, but upon living matter, its phenomena are essentially connected with life itself; and until the properties and contingencies of life be understood in their full extent and bearings, the extent and power of this law will remain undiscovered. Nevertheless, much of its genius is already known.

It will, under favourable influences, especially correct a simple aberration from a condition of health; in spite of great obstacles it will gradually restore; in some instances it succeeds partially, in others it fails; in some it seems to act too powerfully, and, like the viper, inflicts upon itself the sting of death; in all, under circumstances favourable to observation, its benign influence may be more or less recognised.

Here is a field where the explorations of the medical philosopher will be amply rewarded. Well would it be if the lovers and followers of "day dreams" turned the exuberance of their talent to "search it out."

I infer, and am fully persuaded, and am prepared to test the statement with any of the remaining advocates of homœopathy, that in no case has their system proved successful, where simple regard to the diet or the isolated influence of the *vis medicatrix* would not have succeeded, unaided by any homœopathic or any allopathic drug or chemical. In other words: the patient's diet being subjected to proper regulation and surveillance, I am prepared to prove practically and ocularily, that any case, curable as it is supposed by the administration of homœopathic medicine, is equally curable without the exhibition of an atom of medicine of any kind. A disease of the same nature, acute or chronic, existing in two or half a dozen patients, of like age and circumstances, subjected solely to a proper arrangement of diet, air, temperature, and exercise, shall disappear as quickly as when homœopathically treated—in fact, *more quickly*, if the practitioner has a better knowledge than his opponent, of the virtues and influences of those hygienic agents. This I am ready to test: a select and disinterested medical committee, and the profession in general, being the judges. Then, on the contrary, I can select cases, if human life and all its fearful responsibilities were not the cost of the experiment, in which the system of no-medicine and the homœopathic would alike fail, and the allopathic succeed. Here hangs many a sad and doleful tale.

To disregard the accumulation of experience in premature and hasty generalization is a great evil—one which Hahnemann and his followers have committed. Facts are the only basis of accurate knowledge, though not in themselves sufficient without collation and comparison with each other, and with general laws. But when so treated they become "stubborn things." Assertions having the semblance of facts are not wanting; but *bona fide* facts are altogether wanting to prove the oft-vaunted law and the elementary principles of homœopathy. In adopting a system of practice which professes to be superior to others it is not sufficient that it be postulated by a man whose intellect and judgment I may highly estimate. I cannot honestly confide in the *ipse dixit* of a person who half a century ago tried certain drugs which he said produced symptoms or appearances like those of certain diseases. In order to satisfy my mind as to the reality of phenomena, the value of which is intended to supersede the traditional and recorded experience of ages past, and upon which hang interests of the vastest moment, I must witness their occurrence in connection with the repetition of the like experiments. Now, there has been a copious flow of ink wasted in fine-spun speculations and enigmas as to infinitesimal exhalations and impingements of infinitesimal odoriferous particles upon infinitesimally expanded nervous structure; most infinitesimally difficult to be understood even by the most infinitesimally sublimated intellect. But I should like to know of one well-authenticated, undoubted, and modern or recent instance, in which homœopathic belladonna has produced a scarlet rash, or homœopathic cinchona the ague. Here, again, I challenge its disciples to the *experimentum crucis*. I am in a good state of health, and readily disposed, for the sake of science, to become, perhaps, the victim of their folly. But they reply, with all the ready repartee of the sophistry which is ever the handmaid of a bad cause, "No!

(a) Medical Ethics, p. 359. Ed. 1827.

(b) See "Address," published by Churchill.

the onus of disproof rests with the objector; we make statements—he can test them;” or, in reply, they wander far away into those infinitesimal labyrinths into which none but their own infinitesimal thoughts can enter. For example:—one of your correspondents observes—“I have tried eighty-four of their (the homœopaths) medicines, with my corporeal system in an unexceptionable state, and I denounce their system and their statements as a shameless tissue of false assertions.” To which is rejoined—“In the proving of medicines (i.e., in ascertaining their action on the healthy organism), by Hahnemann and others, the *undiluted substances* were employed in doses varying according to the commonly received opinion of their medicinal activity.” This must be a piece of most abject sophistry, easily discoverable by any one who has paid a mere cursory attention to Hahnemann’s writings, or those of his scholars; or the propounder of it must have given less than an infinitesimal effort, to read “that which is written.” He goes on to say:—“Let him who wishes to verify the correctness of Hahnemann’s provings, take a few doses of two or three medicines in the undiluted state—as aconite, belladonna, nuxvomica; and having carefully noted, day by day, the symptoms produced, compare them with those given by Hahnemann. I know that this has been done, and the accuracy of Hahnemann’s provings has thereby been wonderfully corroborated.”

Now, an assertion like this is worth nothing. This is the beginning, the alpha, the fundamental point, the nucleus, the essence of the system. When? Where? How? What? How many are the instances in which “the accuracy of Hahnemann’s provings has thereby been wonderfully corroborated.” Having made this assertion, he then wanders into a maze of subtleties, attenuations, aromas, marsh miasmas, and infantes, mixed up with musk and new hay, into which, as I am not fond of fairies, I shall not follow him; but will return to the sober reflection, that, if the system be not founded on facts, its superstructure must fall. The onus of the proof of these belongs to their promulgators. Show me a scarlet rash produced by the internal administration of “undiluted” belladonna; to be consonant with the law “*similia similibus*,” &c., which it is intended to establish, should it not produce scarlet fever or scarlatina? Show me ague produced by “undiluted” cinchona. Let the experiment be limited to these two propositions. Or go further: show me any other phenomenon said to arise from the use of homœopathic medicine; but let that result be clear, definite, direct; not occult, not needing to be deduced or “made to appear.” Let it be done in my own or in that of any other healthy person; then I shall consider it a signment worth attention, though requiring the recurrence of the same results under the same circumstances, nine times out of ten, or ninety-nine times out of one hundred, to establish the facts beyond all question.

I presume, I hope, I confidently believe there are many sincere and honest men amongst the lovers and practisers of homœopathy, but until the above facts, to say nothing of others which are said to form the crumbling superstructure of the system, be openly tested and established, by every cautious man it must be considered a German chimera, conanguineous to “*chir-voyance*.”

There are numerous cases in which, if the state of society and the mode of remuneration were honest, every honourable-minded, honest-hearted medical man would say:—“The patient must go to bed; regulate the temperature of his room; give him ‘so and so’ for diet; clear out the bowels with a dose of castor oil or rhubarb; other medicine is not necessary.” It is a fact to be remarked, one which I have received from a homœopathic practitioner, that to produce a direct effect, which all could appreciate and understand, a homœopathic dose is not used: a full allopathic dose of oil or rhubarb is given when an aperient is needed. Surely this is being unfaithful and unbelieving to the system—*similia similibus* cu-

rantur—“like cures like.” Why not give a globule or atom of a drug, whose effect is to bind or astringe? To cure ague, you must make it; to cure scarlet fever, you must induce it; to cure costiveness, you should create it.

It may not be necessary to put the patient to bed, but only to arrange the diet, air, temperature and exercise, and means of a psychological nature. In illustration of these views, long known to medical science, and in proof of the utter nullity of homœopathic drugs, I will engage to produce from twenty to thirty cases of bronchitis, influenza, simple continued fever, scarlatina, spasmodic croup, hysteria, anæmia, epilepsy, which have been cured—in some not a particle of medicine having been given, in others by the mere administration of a table-spoonful of *aqua fontaine*—“undiluted water”—three times a day. A learned friend of mine, in a lucid work, “On the Brain,” observes—“The brain has ever seemed to exist as the special instrument of thought; and how much there is implied in that simple proposition—the manifestation of the conscious principle with all its attributes!” Verily, and indeed, there is a vast responsibility implied in a man’s making right use of his brains.

Possessing, then, the consciousness of a conscious principle, with a sincere desire to use it right, I cannot, nevertheless, but feel persuaded that if homœopathy were stripped of its honourable, efficient agencies, diet and hygiene, it would be also either indebted for success to the politic cultivation of a wise and knowing countenance, a shrug of the shoulder; a grave, affected, and sonorous voice; a marked and gradual adulation of the *post hoc*, an increasing disregard of the *propter hoc*, a showy establishment, a carriage and pair, and such-like adjuncts, the common resources of empirics, and of such a character as was faithfully described in “Jerrold’s Journal,” a few months ago. But I am not desiring to pen the “confessions of a homœopathist,” though the strain I have slid into is all but the very words of some of them, uttered, spontaneously articulated, in moments of confession, when the heart sought to be “disburdened of its load.” Such a character is deprecated by the “sincere” and “honest” homœopathist. The most sincere of us, whatever may be his calling, ought to remember the divine declaration: “The heart of man is deceitful above all things;” “who can know it?”

Here I will for the present conclude. At some period hereafter, if I fall not a martyr to homœopathic experiments, I hope to furnish and authenticate the cases treated on the *negopathic* plan.

A. W. CLONE

Grosvenor-street, Manchester, Jun. 23.

ST. GEORGE’S HOSPITAL.

VAPOUR OF ETHER.

The use of the vapour of ether has become so very general now, not only in the London hospitals, but throughout the provinces, that an operation under its influence fails to excite the interest it was wont to do. Nevertheless, a subject of so much importance, not only to the profession, but to every individual in the empire, can lose but little of its interest; and the recital of some operations, and these among the most formidable in surgery, performed while the patients were under the influence of ether, must rouse the fading interest, particularly when the fact is added that three operations were performed with the most perfect success, and without the unhappy sufferers feeling the slightest approach to pain.

At St. George’s Hospital, on Thursday, 25th ult., there was a large assemblage of gentlemen to witness three operations. Amongst those present were observed Lord Morpeth, Prince Jerome Bonaparte, Dr. Paris, Sir B. Brodie, and many others of distinction.

Dr. Snow, in all the cases, administered the ether, and, doubtless, to this and the perfect apparatus may be attributed much of the success.

The first patient was M. F., aged thirty-five.

Scirrhus of the right breast. Mr. Cutler, whose patient she was, performed the operation. In three minutes from the first inspiration of the ether she became insensible; the operation was performed without her showing the slightest symptoms of pain: two or three vessels were secured, and during the whole time she lay perfectly quiet: she neither moved, spoke, nor even moaned. When it was over she could hardly imagine such to be the fact, and subsequently she stated she had a kind of dream, but that she felt no pain, nor any uncomfortable sensation.

The second patient was a lad, aged thirteen, whose knee joint was involved in disease, consequent upon the fracture of the patella some time before. The leg was removed without the exhibition of any symptom of pain, and during the taking up of the vessels he smiled and said, he had not been aware of what was going on. Both of the cases are doing well.

In the third case the efficacy of the vapour of ether was tested more severely. A girl, aged twelve, suffering from strumous disease of the knee-joint, and reduced to a mass of skin and bone, of exceedingly irritable disposition; the approach of the surgeon excited her so much that treatment was almost suspended for want of examination of the knee. By the vapour of ether the joint was examined and its hopeless state made evident. When brought into the theatre she was made insensible in about four minutes. Mr. H. J. Johnson performed the operation very skilfully, and removed the thigh in fifteen seconds; during this time and the subsequent treatment of the stump, she was, like the former patients, totally motionless and insensible, though, when returned to consciousness, her irritability was evinced by abundance of tears.

After the operations, Mr. Johnson made a few remarks on the cases. Lord Morpeth for a few moments inhaled the vapour, but did not seem inclined to go beyond tasting its flavour.

APOTHECARIES’ HALLS.—Gentlemen admitted members March 4:—Patrick Brady, Thomas Orion, William Cumming, Edmund John Burman, and James Graham.

MORTALITY TABLE.

For the Week ending Saturday, March 6, 1847.

Causes of Death.	Total.	Average of 5 Winters.
ALL CAUSES.....	1008	1008
SPECIFIED CAUSES...	1007	1001
Zymotic (or Epidemic, Endemic, and Contagious) Diseases.....	148	183

COURSE OF LECTURES ON CLINICAL MEDICINE,

Delivered in the THEATRE of QUEEN'S COLLEGE, Birmingham.

By SAMUEL WRIGHT, M.D.,

Physician to Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham; Physician to the General Dispensary; Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

Epidemic fevers of 1846; indications of the simplest forms thereof; varieties of these, and observations upon them; particular causes of the simple fever; general causes—atmospheric, telluric, or both; treatment of this fever; advantages of simple treatment; reaction in this form of fever; general and local tendencies of such reaction; anticipations of organic disturbance in fever; observations thereupon; treatment in prospective; cautions concerning it; signs of local lesions; only to be learnt by experience; value of attending to them; cases in illustration; their treatment; illustrations and comments upon them.

GENTLEMEN,—Having concluded our discourse upon the epidemic bowel complaints of 1846, we have now to speak of the epidemic fevers of the same period. During the entire winter of last year, simple continued fever prevailed in this town and neighbourhood to a greater or less extent. As the spring, and summer, and autumn successively advanced, this fever acquired certain pathological modifications, of which we shall speak in necessary detail.

In the most simple and uncomplicated forms of this ailment which you saw, the following symptoms presented themselves. There was considerable depression, both bodily and mental; the patients had an inability, as well as a disinclination, for active exertion; the ideas were confused and irregular, memory weakened, and there was great indecision of purpose. There was seldom any anxiety or apprehension, such as we meet with in typhus and other varieties of fever—the great feature was one of temporary weakness, more or less striking. In some cases the intellectual processes were so enfeebled that the individuals could not fix their attention upon any subject for a few minutes at a time, or even remember, so as to be able to recount them, the events that had most recently transpired. This peculiar state of mind seemed to depend upon nothing more than nervous debility, which incapacitated for action. It was a negative rather than a positive error of intellectual function. There were no strange ideas, no morbid fancies or fears, no raving or muttering delirium, no dreaming or starting in the sleep, and no incoherence, except what might be imputed to the abstraction arising from utter indifference to passing objects or remarks. The patients generally complained of giddiness, but very rarely of pain in the head, and that only temporary, and for the most part after eating. The skin was seldom dry or

harsh, and never very hot; it was usually moist, and often bedewed, especially in the night, with copious perspiration. The surface was pale, features languid: eyes dull, expressionless, and watery; tongue pale and trembling, and sometimes covered with a white fur; pulse small and feeble, and averaging from ninety to one hundred beats per minute; urine scanty; bowels costive; appetite weakened, or wanting altogether; thirst frequent, but not urgent.

This was the simplest and most tractable form in which the fever prevailed here, and hereabouts, during the winter and early spring of last year.

In some instances it was traceable to definite causes—easy of comprehension, such as exposure to night air, sitting or sleeping in a draught, getting the feet wet, over-exertion, over-fasting, and moral circumstances of a depressing nature. But in a vast majority of the cases, no particular cause whatever could be assigned for them; and we could only surmise that some general influence, whether atmospheric or telluric, or both, was in operation. This was the more probable, from the fact that the fever commenced, and continued, and extended, without any seeming relation to locality, to age, sex, occupation, mode of life, or any of the other contingencies that often stand connected with the origin and progress of disease.

The treatment of this fever involved no difficulty. As a rule, those cases of it were best treated which were least so: I mean, which were least troubled with drugging. In a great many of them the ailment ran its course in from four or five days to a fortnight, and then terminated, though no medicines were given; the convalescents shortly recovered their appetites, and these, judiciously gratified, soon restored them to health and strength.

The medicinal treatment, when indicated, was not very comprehensive. If the bowels were obstinate, a dose of calomel, of three or four grains, followed in as many hours by an appropriate dose of senna infusion, compound rhubarb, or jalap powder, fluid magnesia, or colocynth pill, often cut short the ailment, and superseded further physiciking. In other cases, when the bowels were less torpid, but the biliary and other secretions deficient, a milder mercurial, such as five grains of blue pill, or of *hydrargyrum cum creta* sufficed, followed by a gentle aperient of castor oil, rhubarb and magnesia, or something like. When pyrexial symptoms

pointed to febrifuge treatment, this best consisted in restricted vegetable diet, moderate use of toast-water or barley-water, and the exhibition of some such saline as the following:—
R. Sodæ bicarbonatis, potassæ nitratis, vini ipecacuanhæ aa. ʒj; sp. eth. nit., ʒiij; aquæ, vel misturæ camphoræ, ʒviss; ss. fl. mist. cujus capiat, coch. ampla duo tertis horis. If there were no acidity of saliva, or lithic deposit in the urine, the soda could be supplied by half an ounce or an ounce of acetate of ammonia; if there were nausea or vomiting, the ipecacuanha wine was best substituted by eight or ten drops of Scheele's prussic acid, the carbonate of soda being retained.

This form of treatment had the effect of aiding the several secretory functions, especially of the liver, kidneys, and skin, and of anticipating any tendency to febrile reaction. This latter is what you have chiefly to guard against in the management of fever, however simple its type. The skin is apt to become dry and hot, the mouth parched, the eyes red and suffused, and the pulse quick, hard, and bounding. This is an evening exacerbation, common in the cases I speak of; and the great ground of apprehension in it is, either that the symptoms thus increased will continue in severity, or that some organ or other will suffer, and give rise to another and worse train of pathological phenomena. When any particular organic disorder arises out of the general progress of fever, special treatment is instantly indicated, and often none but the most energetic will suffice. It is to anticipate and, if possible, prevent, such an occurrence as this, that, even in the mildest forms of fever, a little judicious management is necessary. To keep up a good action of the kidneys, so as to enable them duly to depurate the blood, and carry from it any morbid matter; to preserve the skin moderately and equally warm, so as to favour a gentle and sustained discharge from its pores, maintain a moderate fulness of its vessels, and thus guard against internal congestions; to free the liver of any accumulations, and unload the intestines of any stagnant irritating fæces; to give appropriate drinks to assuage thirst, and such food as may be best suited to the stomach under these circumstances,—is to answer all the intentions that ordinarily require fulfilment in the treatment of fever. These purposes are best met by doing enough on the one hand, and not doing too much on the other. Always be discretionary in your remedies in such cases—

rather help Nature in what she is about to do, than urge her beyond this by severe measures. When functions are sluggish, prompt them, but still not extravagantly, or you may invite the very mischief you are intending to avert. Desperate purges, or diuretics, or mercurials, or sedatives, will often cause as much organic disturbance, or nervous prostration, as will defy both nature's efforts and your own to compensate.

Sometimes, in spite of your best services, organic derangement or disease will supervene upon simple fever, and call for specific treatment of an active kind. The signs by which these local lesions are manifested, experience and careful observation will alone enable you to understand. It is all-important, however, that you should be able to recognise them directly on their occurrence, so as without loss of time to meet the emergencies which they indicate. These trifles overlooked, often lead to fatal consequences. It is a grave fault to be over officious with remedies when they are little needed; but it is a graver one to withhold those that are called for in exigency. Never, in prejudice or blindness, prejudge the occurrence of organic lesion upon any general disorder, but always be mindful of its possibility, and prepared for its requirements. In the management of fever patients, this discretion will frequently be of service to you. In illustration, let me mention one or two cases that have lately occurred in the hospital.

Mary Ann Frost, a middle-aged married woman, was admitted some weeks back, under my care. She was the subject of simple fever. Her pulse was 130, small and rather firm; tongue pale, trembling, and coated with a sticky perspiration; a feeling of lassitude, and soreness all over; no particular pain in any spot; head moderately cool; pupils natural; no abnormal sounds in the chest, except those of increased circulatory and respiratory function; constant thirst; no appetite; bowels confined. She complained, additionally, of inability to make water. This, however, was not a feature of her general ailment, for she informed me that she had been the subject of occasional retention of urine for some years, especially if she took cold or got her feet wet. There was plenty of urine in the bladder, so that the kidneys were not at fault. The retention appeared to me to be spasmodic, and I therefore ordered her a hip-bath. She passed urine copiously and easily, directly she was placed in it. She had only one return of this difficulty a few days afterwards, and it was relieved by similar treatment. She was directed to take immediately ten grains of jalap and two of calomel, to evacuate her bowels, which she said were habitually torpid. Her further prescription consisted of carbonate of soda and nitrate of potash, one drachm each; nitric ether and tincture of henbane, two drachms each; camphor mixture, eight ounces; of this she was to take two table-spoonfuls every four hours, with one of the following pills. *R.* Hydrarg. chloridi, gr. iij.; pulv. Jacobi veri, ℥j.; ext. hyoscy., q.s. ut fi. pil. viij.

This treatment, you will perceive, had no specific character about it; it was intended to answer the general purposes, for there were no marked particular ones to be fulfilled. On the following morning we found her improved; she had slept comfortably; her pulse was 90, and softer than at first; tongue moist, but still very furred; thirst less troublesome. There were all these favourable appearances, notwithstanding that her bowels had not been opened. I remarked upon this fact at the time, telling you that, *a priori*, I should have expected to have found her more feverish, and with an increase of her general feeling of soreness. In nine cases out of ten this would have been the result of the unrelieved constipation. We were fortunate in not having it so in this instance; but it was additionally desirable not to lose any more time. She was, therefore, ordered an ounce of the sulphate of magnesia, and three drachms of the carbonate, in half a pint of peppermint-water: of this, an ounce was to be taken every hour until the

bowels were well opened. This happened satisfactorily after the fourth dose, and the general symptoms were still further relieved.

On the following day the aching of the limbs was quite gone, so I omitted the henbane from the febrifuge mixture, ordering this to be continued as before, the pills with only every other dose of it, and the cathartic, when necessary, the first thing in a morning.

From this time until the eighth day succeeding her admission she steadily advanced towards convalescence; but on visiting her this day, I found her complaining of a dull heavy pain in the right temple, with occasional shooting pains towards the back part of the head; the pupil of the right eye was considerably more dilated than that of the left, and imperfectly sensible to the stimulus of light; there was slight drowsiness; partial paralysis, and diminished temperature, of the left arm and leg; pulse 60, and somewhat labouring; tongue tremulous, and coated with a thick fur. Here, you observe, we had a train of symptoms and signs totally different from any that had appeared before, and very formidable. What did these things indicate? Enumerate them in your own minds, and you will see that they pointed to local congestion of the brain. There was no evidence to show how this had arisen, but at least the evidences of its existence called for prompt and particular treatment. Eight leeches were ordered to the right temple, and a derivative action was established by means of a turpentine enema, and the immersion of the feet in hot mustard and water. The febrifuge mixture was continued, and with each dose of it two grains of calomel were given. The back of the neck was to be blistered, if the pain in the head were not relieved by the leeching. Fortunately it was, for the next morning she complained little of it; but the state of the pupil, and pulse, and left side of the body, told us that the mischief was not yet overcome. The bowels, partaking of the general sluggishness consequent upon the cerebral oppression, had not acted since the enema was given, and then only slightly. A drop of croton oil, and three grains of calomel, were given at once. In about two hours, these produced a most copious purgation, which was followed by further signs of amendment. The purgative, febrifuge, mercurial, and derivative treatment were continued for a week, at the end of which time there were no evidences whatever of cerebral congestion, or of its more direct consequences. She was then ordered a light vegetable tonic, and nutritive unstimulating diet, under which she rapidly improved, and shortly left the hospital well.

Now, had we overlooked these signs of congestion of the brain, and directed no treatment against it, there can be little doubt that the termination of the case would have been the reverse of what it was. The congestion might have extended, until complete apoplexy had resulted; or, without extending, a vessel might have given way, and fatal insensibility have followed in a moment; it might have run on to inflammation of the substance, or the meninges, of the brain; or, remaining comparatively passive as it was, have proved destructive of serous effusion.

In treating this case, local depletion was preferred to bleeding from the arm, for two reasons: first, because the congestion was evidently limited to a certain extent of the brain, and was rather passive than active in its kind; and secondly, because the general appearance of the patient, her relaxed frame, absence of inflammatory hardness of pulse, and previous impoverished living, told us that sudden or severe exhaustion might have been fatal to her. What the leeching might want in effect, was endeavoured to be supplied by the derivative treatment, as being not only efficacious, but free from the objectionableness of direct depression. The calomel was given, both to act upon the bowels, and to anticipate any absorbent services that might be called for in case of serous effusion.

Another example in pathological bearing, with which you are all familiar, occurred in the

person of the little boy, Gill, who was some time an inmate of the top ward. He was admitted under my care, for simple fever, which exhibited no organic tendencies. Under judicious diet, and mild febrifuge medicines, with occasional laxatives, he steadily progressed towards recovery, for the space of a fortnight: one evening, however, without any forewarning or assignable cause, he was suddenly seized with excruciating pain in the bowels. It chiefly twisted round the navel, and prevented the poor fellow from standing upright on the floor, or lying with his legs straight in bed. Yet he was perpetually tossing in bed and out, to find any position that might be favourable to the relief of his sufferings. There was nausea, but not vomiting, attendant upon this pain, and there was an occasional inclination to tenesmus. Slight pressure, how suddenly soever made, upon the abdomen, did not increase the suffering, but it was augmented proportionately to the amount and continuance of pressure. The pulse was quick, and somewhat firm and full; the tongue vividly red, with strikingly elevated papillae. Mucocentesis was suspected: twelve leeches were ordered to the abdomen, the bleeding to be sustained, first, by hot fomentations, and, subsequently, by poultices of linseed meal. The bowels had been well opened during the day, as also during several previous days; and his medicinal treatment, therefore, was the following:—*R.* Sodæ carbonatis, tinct. opii, aa. 3j.; tinct. hyoscy., 3ij.; aquæ, 3vijsa. M. ft. mist. cujus cap. coch. ampla duo tertia quaque hora, cum pilula. *R.* Hydr. chloridi, gr. j.; ext. papaveris, ℥j. M. ft. pil. viij. In twenty-eight hours all this fresh accession of ailment had subsided, and nothing was left but the general febrile symptoms of which the boy first complained.

George Jones, you will remember, was admitted into the hospital on the same day as the woman Frost, before mentioned. He was the subject of simple fever, and the simplest treatment sufficed for him. He improved under it, and in the course of a week was on the verge of convalescence. On the eighth day succeeding his admission, we found all his febrile symptoms aggravated, and, additionally to these, he had hurried respiration, a short frequent cough, difficult expectoration of tenacious phlegm, and a hard bounding pulse, numbering 126 per minute. The local signs were, dulness on percussion over the situation of the lower part of the right lung, with a crepitant râle in this neighbourhood, and a strong mucous rattle superiorly. This accession of signs, as well as the aggravated symptoms, told us of the supervention of local pneumonia. He was ordered the following:—Ten leeches over the seat of inflammation; the bleeding to be succeeded by a blister, six inches by four in size. *R.* Sodæ carb., vini ipecac. aa. 3jss.; tinct. hyoscy., ap. eth. nit., aa. 3ij.; tinct. humuli, 3ij.; aquæ, 3vij.; misce, ft. mist. cujus cap. coch. ampla duo tertia hodie, cum pilula. *R.* Hydrarg. chloridi, gr. iij.; pulv. Jacobi veri, ℥j.; aet. morphine, gr. j.; ext. conii, q.s. ut fi. pil. viij.

Under this form of treatment, he speedily and satisfactorily improved, and in a few days was suffering only from the general fever for which he came into the hospital. But the dulness on percussion never subsided from the situation where the inflammatory action was first indicated, and the respiratory sound here was almost exclusively tubular. This was due to the condensation of pulmonic tissue, which even in this short space of time had resulted from the inflammatory process and its products; the passage of air was limited to the bronchial branches. Still this was not a serious evil, inasmuch as there was plenty of lung on either side to answer all the purposes of even healthy respiration. The sound parts of the lungs are capable, to a certain extent, of being supplemental to the obstructed parts; and thus are the emergencies of these organs often answered. So it appeared to be with this man; for, after the subsidence of his pneumonia, he advanced as

steadily towards recovery as he had done after the cessation of his early febrile symptoms. But, poor fellow, he seemed fated to die in the hospital: for directly that he became the subject rather of the *materia alimenticia* than the *materia medica*, he stumbled in the lobby one night, in the dark, and fell violently with his left temple against a sharp corner. You remember what a local tumefaction and black eye he had the next morning. The cerebral symptoms were not severe, but he never recovered the shock: his vital powers were prostrated from this time; his pulse never acquired any tone, nor did the discoloration of his eye disappear during the further month that he lived. The concussion killed him, though it was very slowly. The pathological features of this case I shall consider on a future occasion.

DUMAS ON ORGANIC CHEMISTRY. No. XLV.

ON THE URINE. (Continued from p. 39.)

We can have no difficulty in at once perceiving that the function of the kidneys must be to a certain extent modified by the age and sex of the individual, and also, in an especial manner, by the kind of regimen which may have been adopted. The influence which these different conditions exercise over the secretion of the urine has been studied by various observers, and more especially by M. Lecanu, who has devoted great attention to this subject. His experiments were performed on sixteen individuals, of different ages and sex, namely:—

6 men	from 20 to 45 years
2 old men	" 84 to 86 "
4 women	" 18 to 28 "
4 children	

The density of the urine examined by M. Lecanu varied in a remarkable manner. Annexed are the extremes of these variations, calculated on ninety-three samples representing the entire quantity of urine voided during one day by the above sixteen individuals:—

4 times the urine off red a density	
1. prior to	1.016
31 " " " ranging between 1.016 and 1.030	1.030
44 " " " " 1.030 and 1.030	1.030
11 " " " " higher than 1.030	1.030

The urine of man, when in the prime of life, is always found to be denser than that of women or of children. We may, moreover, remark that in man the amount of urine secreted is, *rotaris paribus*, greater than in the other sex. The quantity of urine voided by thirteen individuals of different ages and sex, who were living well, but were subjected to different external influences, varied from 525 grammes to 2 kilograms—271 grammes, daily. In individuals of the masculine sex, and at the middle age, the urine is secreted more copiously than in old men, in children, and often, even, than in women.

By comparing the quantity of urine given by five men, between twenty and forty-five years of age, during several consecutive days, I have found a mean ranging between 743 and 2271 grammes. These differences are less than in the thirteen cases which furnished the numbers from 525 to 2271. The variations were even less marked in three individuals, respectively of the ages of twenty, twenty-two, and thirty-eight years, in whom the urine was collected for several days in succession.

	Kilo.
The first gave in 12 days	11.969
The second " 12 "	11.572
The third " 8 " 7.623, equal, in 12 days, to 11.433	11.433

Lastly, these same individuals, when placed under similar external influences, voided equal quantities of urine.

M. Lecanu also quotes, on this subject, the following experiments:—

In 6 days, a person furnished	Kilo.	In 6 other days	Kilo.
6 " " " " " " " " " " " "	5.939	6 " " " " " " " " " " " "	5.713
5 " " " " " " " " " " " "	10.036	5 " " " " " " " " " " " "	9.859
3 " " " " " " " " " " " "	1.977	3 " " " " " " " " " " " "	1.916
4 " " " " " " " " " " " "	3.897	4 " " " " " " " " " " " "	3.653

The mean of the above forty-eight experiments

gives 1268 grammes of urine. But, in some, the quantity of urine secreted never reached this figure; in others it invariably exceeded it. This circumstance explains why various observers, who have made calculations on this subject, have arrived at such different results. In fact, the quantity of urine secreted in twenty-four hours has been, by Haller, set down at 1688 grammes; by Bostock, at 1280; by Proust, at 1040; by Thomson, at 1610; and by Rayer, at 1267 grammes.

Let us now compare the proportion of urea contained in the urine of various individuals, collected during several consecutive days. The following table is extracted from the work of M. Lecanu:—

In 12 days, a man, aged 20, furnished 334 grammes of urea.	
" " " " " " " " " " " "	334
" " " " " " " " " " " "	310
" " " " " " " " " " " "	351
" " " " " " " " " " " "	361
" a woman " " " " " " " " " " " "	205
" " " " " " " " " " " "	210
" a child " " " " " " " " " " " "	171
" " " " " " " " " " " "	168

M. Lecanu deducts the urea from the given weight of nitrate of urea; he considers 100 parts of this salt to be formed by:—

Urea	53.50
Nitric acid	46.50

Now, the experiments of M. Regnault have proved that urea takes up an equivalent of water, while combining itself with bases; this will consequently give:—

C ² H ⁴ Az O ² =	60	— 48.8
Az O ² , HO =	63	— 51.2

123 100.0

The urea is then valued too high, by about a tenth, in the experiments of M. Lecanu. But this is not of great consequence, inasmuch as the memoir of M. Lecanu is rather designed to show the direction of the variations of the urea than the absolute quantities of this principle.

The amount of urea secreted is much greater in men in the prime of life than in women, old men, or children. It is also more considerable in women than in children and aged people. Annexed are some calculations as to the quantity of this principle yielded in twenty-four hours:—

	Mean.	Maximum.	Minimum.
Man	28.0	33.0	23.1
Woman	19.1	28.3	9.9
Old man	8.1	12.2	3.9
Child of 8 years ..	13.4	16.4	10.4
Child of 4 years ..	4.5	5.3	3.7

We know that the urine of very young children does not contain any appreciable amount of urea; and I am inclined to believe that that of convalescents will be found in the same condition, or at least that it will resemble the urine of children a little more advanced in years.

The quantity of free acid which is found in the urine varies remarkably. In general, we may state that one pint (French) of urine is capable of being saturated by one gramme of carbonate of soda; the most acid urine which M. Lecanu has met with never required more than 2.75 grammes.

The secretion of uric acid varies according to the age, diet, sex, &c., of the individual, within the limits of 0.089 and 1.575 grammes daily; but the difference which exists, by reason of age and sex, is here greater than we find to be the case with regard to the quantity of urea, although it sometimes happens that individuals of the same habit, age, and sex, furnish, during a similar space of time, apparently equal quantities of uric acid.

	Uric acid secreted in 12 days.

We see, according to this table, that the production of uric acid does not follow so regular a course as that of urea; and this may be readily conceived, when we consider that the production of uric acid is merely an accident arising from the circumstance that a portion of the neutral azotized matters have been but imperfectly burned. We know, in fact, that uric acid is a less oxidized body than urea.

The proportion of mucus has been found by M. Lecanu to vary considerably: in the four men, mentioned in a former experiment, who were aged, respectively, twenty, twenty-two, thirty-eight, and forty-three years, it amounted to 1.13, 1.72, 1.27, and 1.63 grammes; a fifth man, who was remarkably robust, yielded but 0.312, and another only 0.478 grammes. In several women and old men, it ranged from 0.29 to 0.375. With children the quantity furnished was quite inappreciable.

We shall hereafter find, in pursuing our investigations as to the matters which pass off by the urine, that the quantities of fixed salts, voided in twenty-four hours by the urine, vary considerably. In fact, by experiments performed on eleven individuals, these materials were proved to fluctuate between 4.84 and 24.6 grammes; these variations were even observed on the same person; still, under normal conditions of diet, &c., we may in general remark, that these saline matters are more considerable in men in the prime of life than in women, children, or aged persons; and this is not difficult of comprehension, if we bear in mind that men usually take a much larger quantity of nutriment, charged with fixed salts, &c.

	Mean.	Maximum.	Minimum.
Man	16.8	24.6	9.9
Woman	14.3	19.6	10.7
Child of 8 years ..	10.0	10.9	9.9
Old man	8.0	9.7	4.8

Among the salts, the earthy phosphates have presented the greatest variations, and which cannot be said to have borne any relation to the sex or age of the individual; their weight fluctuated between 1.960 and 0.029 grammes. M. Donné has observed that the urine of pregnant women contains a less amount of earthy phosphates than that which is found in ordinary urine. Fourcroy stated his opinion, that the urine of old men contains the largest quantity of salts, and especially of earthy phosphates. MM. Guibourt and Rayer affirm the contrary. M. Lecanu has, by analysis, found the urine of children more loaded with earthy phosphates than that of old men, although the urine of one of these latter, when experimented on, was remarkably acid.

The quantity of chloride of sodium rendered daily by the urine, in different individuals, varies from 0.016 to 7.550 grammes. These variations are seldom so great in one individual, but still they may range from two to five grammes in the day. The amount of this salt has been found to be sensibly the same in man, at the middle age, and in the child; but in old men and in women it decreases in so remarkable a manner, that it is impossible to attribute the difference observed to mere errors of experiment. The women, moreover, had fared on the same diet as the men. Whilst, then, the man yielded by the urine from 2.9 to 4.6 grammes of chloride of sodium, the woman voided no more than from 0.690 to even less than 0.017 grammes. Proust has noticed that the urine of dying persons is almost entirely deprived of this salt—a fact which accords with its progressive diminution in the advanced stages of life.

The quantity of the soluble phosphates varies, in the same individual, from 0.111 to 4.643 grammes in the day; nor does it appear to be regulated by age or sex. Generally speaking, it but rarely exceeds one gramme.

The sulphuric acid which is held by the urine in the state of a soluble sulphate fluctuates, in the same manner, from 1.988 to 3.730 grammes.

The following are the conclusions drawn by M. Lecanu on this subject.

Urea and uric acid are secreted in equal quantities during given periods, in the same individual. The quantity of urea secreted by

different individuals, during equal periods, varies in respect to sex and age: being greater in man in the full vigour of life than in woman, and more considerable with the latter than in old men and children. Those materials which are indecomposable by heat, and

which are found to be secreted during a given time by different individuals, vary without any relation to sex or age, and even present remarkable changes in the same individual. The general results of the experiments of M. Lecanu are given in the following table:—

Products voided in twenty-four hours.	Child of four years.	Child of eight years.	Man.	Old man.	Woman.
	Grammes.	Grammes.	Grammes.	Grammes.	Grammes.
Uric acid	—	0.15 to 0.25	0.30 to 1.0	0.20 to 0.50	0.30 to 0.60
Urea	3 to 5	10 to 16	23 to 33	4 to 12	10 to 28
Salts	—	10	10 to 25	5 to 10	10 to 20
Chloride of sodium	—	2 to 5	4 to 7	0.4 to 1.5	0.1 to 0.7
Barthy phosphates	—	0.3 to 1.3	0.4 to 2.0	0.2	0.2 to 2.0

We have now to study the influence which drinks, solid aliments, and other matters, when accidentally introduced into the system, exercise over the urinary secretion. Every one knows that the ingestion of a large quantity of water into the economy immediately augments the secretion of urine. It has been remarked that, under these circumstances, the urine becomes clearer, and that its density diminishes. It would, indeed, be difficult to understand how it could be otherwise. The excess of water introduced into the stomach passes rapidly into the current of the circulation, without exercising the least influence over the secretion of urea and the other organic materials of the urine. All that it can do is to charge itself with the salts which it meets with in the economy, and thus to augment, in a slight proportion, the quantity of inorganic materials excreted during a given time.

It is generally admitted that the nature and quantity of the aliments exercise a great influence over the urinary secretion. This fact is incontrovertible, although, perhaps, it has been exaggerated by some observers. Indeed, it is impossible to maintain that it is at the expense of the aliments alone that the urea and other organic materials of the urine are created. The formation of these principles is continued during the lowest or most restricted diet which is imposed in certain diseases, or even during the periods of forced fasting to which animals are sometimes submitted. We have already stated that its origin must be attributed to the metamorphoses which the materials of the organism, on being taken up by the returning or impoverished blood, experience as an effect of respiration. However, it is clear that wherever an excess of the reparative materials is introduced into the economy, as under the influence of too full a diet, a part of the azotized materials of which the nourishment is composed is directly eliminated by the urine under the form of urea.

On the other hand, the varied aliments, to which the progress of civilization has gradually habituated us, introduce into the economy a variety of azotized substances which are incapable of serving in a direct manner for the nutrition of our tissues. The assimilative powers of the organism, however active they may be, can never transform *these* into flesh. This substance, like many others of an analogous character, can only perform a secondary part in the great act of nutrition: and it is probable that, after serving the requirements of respiration, these matters concur directly in the formation of urea. Hence we may understand the influence which aliments exercise over the urinary secretion.

M. Chossat has proved that the solid materials of the urine vary, not only with a given weight of aliments of the same nature, but like wise with aliments of different kinds, when taken in the same quantity. On the other hand, MM. Simon and Lehmann have shown that the proportion of urea is augmented in the urine by an abundant azotized nutriment, and that it diminishes under the opposite condition.

Among the matters introduced into the economy, in an accidental manner, there are some which pass off by the urine, either in their

natural state, or after having undergone a greater or less amount of alteration, whilst others are not met with in this liquid at all.

M. Woehler has performed a number of experiments on this subject. According to this chemist, the colouring matters of rhubarb, madder, logwood, beetroot, mulberries, black cherries, the sulphate of indigo, gunboge, &c., pass into the urine, giving it a deep colour. Asparagus communicates to it a peculiar foetid odour, which results from the partial decomposition of certain materials contained in it. Many essential oils, as those of the juniper-berry and of garlic, pass off by the urine; spirits of turpentine, certain resins and balsams, communicate to it a smell of violets. Opium, copaiba, assaetida, and saffron, give their peculiar odour to this fluid. The carbonates, sulphates, chlorates, sulpho-cyanurets, nitrates, and phosphates pass off by the urine without alteration.

According to M. Cantu, mercury is found in remarkable quantity in the urine of individuals when undergoing a mercurial treatment. The preparations of gold, antimony, and arsenic are eliminated in great part by the urine; iodine passes into it in the state of an ioduret; sulphur, sulphuretted hydrogen, and the sulphurets are found there, but in the state of sulphates. Generally speaking, the ingested products pass into the urine after having undergone a true oxidation. The red ferro-cyanuret of potassium, however, is met with in this fluid in the form of a yellow ferro-cyanuret, while the latter salt passes into it without alteration.

It is a difficult matter to acidulate the urine by means of the organic acids, for they are in great part destroyed within the system. Thus, the citrates, the malates, and the acetates are burned within the economy and reduced to the state of carbonates; the urine will, consequently, often become alkaline after the administration of these salts, even when they contain an excess of acid. We have only to eat ripe fruits, as strawberries or cherries, which contain tartarates or citrates, to observe this alkaline reaction manifest itself in the urine.

Benzoic acid undergoes a very remarkable transformation in the economy; we find it in the urine in the state of hippuric acid combined with bases. Dr. Ure was the first to draw attention to this fact, which has since been confirmed by M. Keller. Benzoic acid, then, combines itself in the economy with some azotized body arising from the metamorphosis of the tissues, and it is afterwards eliminated in the state of hippuric acid. This fact becomes of great importance in a physiological point of view, by demonstrating that certain non-azotized principles of our economy may intervene in a direct manner in the transformations which the azotized matters of the organism undergo.

The preparations of iron, lead, and copper, alcohol, ether, camphor, musk, the colouring matter of cochineal, litmus, alkanet, &c., are never found in the urine. The same may be said with regard to a great number of inorganic matters; many of them undergo an immediate decomposition within the digestive tube, which, by rendering them insoluble, prevents their absorption and passage into the blood.

SUBSTANCE OF A LECTURE

By Mr B. BROWN, M.D.

ON SOME DISEASES OF THE SHOULDER-JOINT, AND CONCLUSION. REMARKS ON COUNTER-IRRITANTS.

GENTLEMEN,—In my last lecture, when speaking of diseases of the shoulder-joint, there was a peculiar consequence which I was unable to notice. I should have said, when speaking of scrofulous diseases of this joint, that it is often followed by dislocation, just as happens in the case of diseases of the knee or hip-joint.

When I was first assistant-surgeon, or, I think, when I was a student, I saw a boy brought in who had a dislocation of the shoulder. It was no common dislocation, for the head of the bone stuck out directly forward. The surgeon who attended the case supposed that it was the result of maltreatment by the practitioner who had previously been attending the patient. The boy died in the hospital, and an opportunity was afforded for examining the body. We found scrofulous disease of the bone, the head of which had been absorbed, and the glenoid cavity, in its anterior part, destroyed.

In another case a young lady had scrofulous disease of this joint, and I recommended a leather splint, made and applied in the way that such splints usually are—wetted, and adapted to the form of the part, and then dried, the arm being bound up to the side. The case went on well for a long time, but, as the lady afterwards went abroad, I was unable to trace it further.

There is a peculiar disease of the shoulder-joint, brought on by the wasting away of the deltoid muscle, the consequence of which is a paralytic affection of the arm. This is not properly a disease of the shoulder-joint, but, as it is very liable to be mistaken for it, I shall make it the subject of a few remarks. It is not uncommonly a consequence of dislocation, and I suppose that the circumflex nerve is torn by the head of the humerus, and thus the deltoid muscle is paralyzed; it is often the cause of great perplexity to surgeons. A gentleman whom I know well and dislocated his shoulder; he consulted a practitioner of eminence, about eighty miles from town, who reduced it very properly. Some time after this the gentleman lost the power of using his arm, and the shoulder was evidently getting smaller; he consulted another surgeon, who said it was an unfortunate case, as it was an unreduced dislocation of the shoulder, and that the time was gone by for reducing it. This brought much blame on the gentleman who had been first in attendance upon the patient. Not long afterwards, some other cause produced the death of the gentleman whose shoulder had been dislocated, and the surgeon who had first attended wished to examine the shoulder, which he did. The head of the bone was found in its place, showing that the dislocation had been properly reduced; but the deltoid muscle had wasted away, almost to nothing, and this, causing the appearance of hollowiness under the head of the acromion, had induced the opinion that the dislocation had not been reduced.

I remember a lady, who, a fortnight after her confinement, had a strong pain in the shoulder-joint, extending from the coracoid process to the back of the scapula. The pain continued forty-eight hours, and then subsided, but when that was gone she had no power of raising her arm. The deltoid muscle was paralyzed, and I believe she never regained the use of her arm. Inflammation, as I think, of the circumflex nerve took place, which became so disorganized as to lose its influence.

Another disease connected with the shoulder-joint, and of frequent occurrence is very important to be understood. The patient comes with a great tumour in the region of this joint, not always of the same size, containing fluid. It will probably come out, on inquiry, that this tumour has been a long time forming, and has gained its present size slowly. As I said, it appears to contain fluid, and if you puncture it serum escapes, with lymph floating in it; at other times it is like

Bursitis. This tumour is the result of inflammation in one of the humerus bursae about the shoulder-joint, and corresponds to the disease which occurs about the knee-joint from a similar cause. You can never tell by the appearance of the tumour in what exact bursa the disease originated: in one case these bursae may be situated beneath the muscles and tendons, and, when the tumour has become enlarged, it passes away to a spot where less opposition is offered, and quickly increases in size. Thus I have known a bursa between the psoas muscle and the bone become inflamed and swell; the fluid passes down the course of the tendon, and makes its way outward amongst the parts connected with the gluteus maximus, forming a very large tumour. So also you will sometimes find one of these bursae about the shoulder-joint, enlarging till it makes its way under the scapula or under the edge of the trapezius muscle; it is therefore not uncommon to find this disease situated at some distance from the point where it had its origin. Suppose in one of these cases a tumour is formed by the fluid in a bursa between the latissimus dorsi and the inferior edge of the scapula: you then have the swelling in the place which it might have occupied had a bursa near the shoulder been the seat of disease. You must be very careful what you do with these bursae near the shoulder-joint; for, if inflammation supervene upon an operation, it extends over a very large surface. In one such a case I punctured a bursa to make an opening by which the fluid might escape, and did not take the trouble to squeeze it out; I bound up the arm, serum continued to come away, and the case did well. When I was assistant-surgeon, there was a patient in this hospital in whom one of these bursae had been opened, and inflammation had followed; I do not know whether he died or not, but I am sure that he was in very great danger. In another case which I saw, a surgeon ran a seton several inches in length through the swelling, and there left it; inflammation, attended with great constitutional disturbance, followed, and the patient died. In another case the patient died in consequence of the opening and rough handling of a bursa of this kind. This rough handling you must invariably avoid; but when the tumour is of large size, the necessity is even greater, and the greatest caution will be requisite in making an opening. I saw, in consultation with another surgeon, a large bursa near the hip-joint, under the edge of the gluteus maximus; the lining membrane was to a great extent inflamed; we agreed to puncture it. The patient was very ill, and an attack of rheumatic fever followed, which, I think, was brought on by the inflammation of the bursa. You may do good by merely opening the cyst, and allowing the fluid to run out, as it has a tendency to do; when this has been done, tie up the arm, and, if it is disposed to heal, let it do so, and, if it seems inclined to remain open, leave it to do so. Perhaps the cyst may gradually contract, granulate, and heal. I am, I may say, inclined in these cases to avoid operations; and I think you may often do much good by merely tying up the arm, so as to keep it perfectly quiet, and applying a blister over the tumour. I do not say that you will thus be sure of getting entirely rid of it, but, if this treatment be kept up for any length of time, it may be considerably reduced.

Having offered these observations upon diseases of the shoulder-joint, I shall proceed to bring to a conclusion the remarks which I commenced in a previous lecture in connection with the subject of local stimulants or counter-irritants. As I have already spoken of blisters and liniments, it only remains to consider the uses of setons, issues, and moxas in surgical practice. I need not tell you what a seton is, or how it is made. I may just say, with respect to issues, that the old way of making them was to divide the skin with a lancet or bistoury, and introduce peas, beans, or beads, or some other substance which would hinder the sore from healing, and serve to maintain suppuration. A more usual

method now is to rub the surface of the skin with caustic potash or nitric acid till you bring on sloughing of the cellular or adipose membrane; after a few days the slough will come away, and the sore thus formed is kept open by artificial means, as by peas or beads, which are put in daily. The introduction of these is often very inconvenient, and another mode of keeping the issue open is by some surgeons adopted, and which in local disease is preferable to any other: the sore is dressed every day with simple cerate, and once a week is touched with caustic potash. Setons and issues have been recommended, both in medical and surgical practice, to accomplish two distinct purposes—sometimes with the view of relieving the blood of some supposed poison, and thus of preventing the occurrence of scrofulous disease; at other times, with a view to act on merely some local affection. With respect to the general effect on the constitution, I cannot find that any very beneficial results have followed their use. Suppose a man comes to the hospital with scrofulous disease of the ankle or knee, and in other respects he is very well; this ankle or knee is amputated, and the stump heals, but the man gets disease of the lungs, and dies—the limb, which had acted as a drain on the system, being removed. I cannot say that, in the case of a person so affected, I think in these cases issues or setons are of much benefit. I am aware that many surgeons think that they act as a drain for any noxious matter existing in the system, but according to my experience the seton or issue never answers a purpose similar to that which we find accomplished by the scrofulous ankle or knee; in fact, the discharge from an issue is not of scrofulous matter at all; a person may have a large suppurating wound, but it does not act as the scrofulous knee, and if it swells, and weakens the system, it makes him actually worse. With respect to the operation of setons and issues in local disease, I have not the slightest doubt of their beneficial results, nevertheless the cases in which they are serviceable are not numerous; in chronic determination of blood to the head, there can be no doubt of their beneficial effect when inserted in the back of the neck. Medical men are in the habit of employing issues in cases of diseased kidney, placing one in the loins. In certain of these cases—not the tubercular or Bright's disease, but simple chronic inflammation—I have known an almost immediate effect follow their use. Even when the power of voiding urine has been completely lost, the application of a seton has restored it. I knew a gentleman, having disease of the kidney of the chronic kind, who, with his urine, voided large quantities of lymph, attended with pain. This state of things had existed for a long time. I made a large issue in the loins with caustic potash, keeping it open with peas, and from the time when the discharge might be considered established, no more lymph was voided with the urine. He ultimately died of diseased kidney, and of stone in the bladder, but never had any secretion of lymph. It is chiefly, however, in disease of joints that the necessity of the use of these stimulants is met with in surgical practice; and, from all the observations I have made, I can say they are then of great value. Of the two kinds I prefer the caustic issue. There are two periods at which I think the effect of the caustic is most beneficial: the first, when it is first applied; the second, when the slough separates and the discharge commences. But in what cases of diseased joints are these applications most indicated? If there be ulceration of the cartilage, independently of scrofulous disease of bone; where there is ulceration of the cartilage in consequence of inflammation of the synovial membrane; and where there is primary ulceration of the cartilage, depending, as I believe, in general, on rheumatic inflammation of the harder texture. In these cases I think they are very useful applications. How these kinds of disease are to be distinguished in practice I informed you in the last lecture: when the cartilage ulcerates in connection with scrofulous disease there is very

little pain; but in those cases where the bone retains its natural texture, and ulceration is a primary disease, or comes on in consequence of inflammation in the synovial membrane, there the pain is very great in the joint itself, with painful starting in the limb. In such cases as these the issue is useful—not that I always use the caustic, for it is not always required; mercury and sarsaparilla will be sufficient, and, as the caustic is a painful remedy, it is better not to use it when it can be dispensed with. In some cases of diseased spine the caustic is very useful—those, for instance, corresponding to primary ulceration of cartilage, where the bones have their natural texture; and where, as I believe, caries begins, not in the bones themselves, but in the intervertebral cartilage: these I believe also to be chronic and rheumatic affection of the tender textures of the spine. Though this case is difficult sometimes to ascertain in the living person, there are three ways in which it may be done—first, by observing whether the case presents the marks of scrofulous disease; second, by the age of the patient, as it occurs principally in the old, while scrofulous disease is seen mostly in the young; and third, by the degree of pain, which is very great, while in scrofulous disease there is often none at all.

It used to be the custom to make setons and issues in a great number of cases, where now they are thought unnecessary, if not injurious. When a patient came into the hospital, with disease of the hip or knee, I remember, when young, it was said—"This is a hip case, or this is a white swelling; let a blister be applied, or an issue made." If the patient came with scrofulous caries of the spine, or angular curvature, the immediate exclamation was—"This is one of Pott's cases—make an issue;" and, I believe, in nine cases out of ten, they did more harm than good. After a large experience in cases of scrofulous disease of the joints, I venture to say, that whatever the case may be, they do harm instead of good, because the patient is weak before the sore is made; and its effect is to make him still weaker, by the constant drain on the system which their discharge promotes. If an issue be made, it requires to be rubbed with caustic potash every now and then, to keep it open; the sore is thus a means of constant distress to the patient, especially if it be a child, who the whole day anticipates with dread the approach of the time of dressing, which tends very much to impair the general health. Those other occasions for the use of these counter-irritants, as they occur chiefly in medical practice, I need not here enumerate.

Another method of producing counter-irritation I will just mention: you make a slough by means of the actual cautery, or the application of a piece of red-hot iron. I have tried this a long time in order to satisfy myself of its value. The iron is applied just as the red heat is going off; it burns the skin, and, according as it is kept in contact a longer or shorter time, it makes a thick or thin slough. When the slough comes away you may keep it open, make it an issue, or let it heal, and apply it again elsewhere. The caustic has this advantage, that it terrifies the patient less than the cautery; Englishmen have a great dislike to such a remedy. Sir A. Cooper used to call it a rude piece of farriery; and, perhaps, he was not far wrong.

Another way of making counter-irritation is by burning cotton on the skin for a certain time: this is called a *moxa*. Sometimes the material is dipped in a solution of nitrate of potash; the surgeon blows on it by means of a blowpipe, till, heating the part more and more, it destroys the organization, and makes a slough more gradually than the hot iron, and not so thick, indeed scarcely thick enough for an issue. It has been the custom to make with the moxa, first one slough and then another, and so on. I am not aware that this has any advantage over the other methods of counter-irritation; and this seems to be the general opinion in England, though on the Continent it is much in use. There is another way of applying moxas which has

some advantages over the one just described. I have generally employed what is called German tinder, which is sold in the shops for lighting cigars. I first cut it into small pieces, and then, tying a portion tightly with a bit of thread, and laying it on the part where the issue is intended to be made, holding the tinder all the time with a pair of forceps, I light it at the top and let it burn, which it does very slowly, and blowing it by means of the blow-pipe till the patient complains, when you remove it. In this manner blister after blister may be made. Of course a slough may be made as well with the moxa, but I am supposing that you do not apply the heat a sufficient time to cause sloughing, but only a blister, which will soon heal. This is a method in some respects preferable in cases of diseased joints and of inflammation of the synovial membrane, especially as it is less painful and troublesome than the moxa. They may be kept open like any other sore, by rubbing with potassa fusa, repeated nearly every day.

With these observations my lectures for this season conclude; and, with my best wishes for your success in your studies, I take my leave of you for a time.

ORIGINAL CONTRIBUTIONS.

OBSERVATIONS ON URINARY CALCULI, AND ON LITHOTOMY.

By F. H. BRETT, Esq., M.D., F.R.C.S.,

Member of the Royal Asiatic Society; late Surgeon to the Governor-General of India's Body Guard, and Government Ophthalmic Hospital, Calcutta.

Introductory remarks; statistics of lithotomy; remarks on the varieties of urinary calculi; on the causes of urinary calculi; on the great frequency of the disease in India; size and figures of calculi; symptoms of calculi; on the operation of sounding; on the extraction of minute calculi. Case—mode of operating for lithotomy; introduction of the forceps; bilateral section; treatment of the fragments; method of crushing the stone when large.

AFTER-TREATMENT; OBSERVATIONS; CASE OF ENCYSTED CALCULUS; CASE OF "OPERATION A DREX TEMPS"; CURIOUSLY FORMED CALCULUS; TETANUS; PERITONITIS.

INTRODUCTORY REMARKS.

The statistics of lithotomy exhibit instances of the great success of this operation in experienced hands; they also adduce a fearful record of average failures. Did, we follow the first it would seldom be requisite to resort to the modern operation of lithotomy. On the other hand, we cannot reflect on the average fatality in some hospitals, and under some lithotomists, without a blush and a sigh. I trust I may be permitted to quote the result of 108 operations. The proportion of fatal cases in the first thirty-eight is very considerable, being seven out of that number. The last seventy cases afford a far greater subject for congratulation, having all recovered. The experienced surgeon speaks of the operation of lithotomy, especially in children, as one which ought not to be dangerous. We have now the power of preventing the pain, the knowledge of the appalling ceremony, the shock! We can, in fact, make the operation itself a dream of pleasure. In the child we have not even the dread by anticipation.

URINARY CALCULI.

It is only when deposits originally formed in the kidneys have passed into the bladder that they become the subject of surgical attention. It will be seen how little the varieties of calculi in India differ from those in Europe. They are exceedingly various in their composition. Some of them, the uric acid for instance, and the phosphates, are the natural constituents of the urinary secretion; whilst others are the results of new combinations of its elements, as the

oxalate of lime, and the cystic oxide. The most prevalent dispositions of the system to these deposits have been termed the lithic or uric, and the phosphatic diatheses. (Prout.)

The "lithic acid diathesis," by far the most common, is characterized by the deposition of

red particles (whether amorphous or crystalline), and lithic concretions of a whitish brown, or mahogany colour, in laminae or strata soluble by solution of the alkalis. If a small portion of nitric acid be added, and the whole evaporated to dryness, it assumes a beautiful carmine colour.

Statistical Record of the Lateral Operation of Lithotomy in India, by F. H. BRETT.

Number	Date of Operation.	Name and Caste.	Age.		Duration of Disease.		Result and Remarks.
			Y.	M.	Y.	M.	
1	Oct., 1827	A Moosulman Child ..	8	0	3	0	Successful.
2	Oct., 1828	Maknun Brahmin Child ..	4	0	3	0	Ditto.
3	March, 1829	Kissoona Hindoo ..	35	0	30	0	Died a month after the operation, constitution having been much impaired from thirty years of acute suffering.
4	April, 1829	Hindoo (Brahmin) ..	17	0	10	0	Tetanus, which on the 11th day proved fatal.
5	21 April, 1829	Hindoo Child ..	3	6	1	0	Successful.
6	Oct., 1829	A Hindoo Child ..	7	0	3	0	Ditto.
7	17 Feb., 1830	Dhunna Hindoo ..	5	0	2	0	Ditto.
8	21 April, 1831	Pestun Hindoo ..	6	0	5	0	Ditto.
9	3 Nov., 1831	Khoondun Hindoo ..	7	0	1	0	Ditto.
10	29 Nov., 1831	Jijona Moosulman ..	6	0	4	0	Ditto.
11	9 Dec., 1831	Bhujona Hindoo ..	8	0	8	0	Ditto.
12	21 Dec., 1831	Zoorra Hindoo ..	4	0	1	0	Ditto.
13	28 Jan., 1832	Gholamie Moosulman ..	3	9	2	0	Died of peritonitis on the second day.
14	28 Jan., 1832	Munna Brahmin ..	20	0	11	0	Successful.
15	14 April, 1832	Motie Chugun Brahmin ..	12	0	4	0	Ditto.
16	16 May, 1832	Nawla Hindoo ..	18	0	6	0	Ditto.
17	2 July, 1832	Bhimma Hindoo ..	30	0	1	0	Ditto.
18	11 July, 1832	Rahman Brahmin ..	7	6	6	0	Ditto.
19	11 Aug., 1832	Nunda Hindoo ..	14	0	7	0	Ditto.
20	13 Aug., 1832	Juwahir Rajpoot ..	23	0	10	0	Ditto.
21	13 Aug., 1832	Lallae Hindoo ..	9	0	4	0	Ditto.
22	23 Aug., 1832	Cho reva Hindoo ..	60	0	8	0	Died of hemorrhage from irregular distribution of the internal pudic artery, which was very profuse.
23	Sept., 1832	Poosa Telia ..	60	0	8	0	Successful.
24	Sept., 1832	Ramzan Dhanook ..	26	0	5	0	Ditto.

In the "phosphatic diathesis" the phosphate of ammonia and magnesia predominates. It is the result of an impaired constitution, rather than a primary affection. It is sometimes termed the triple phosphate, has a white chalky appearance, and is soluble in acids. It generally forms the exterior of calculi, whilst the interior is ordinarily composed of the lithic acid, or lithate of ammonia. The triple phosphate is covered with minute shining crystals; it is easily pulverized—but occasionally hard, compact, and crystallized in texture.

The "lithate of ammonia" is likewise by no means uncommon. It is of a clay colour, composed of concentric layers, and confined principally to children. It is soluble and alkalis and alkaline carbonates, and emits the odour of ammonia when treated with caustic potass.

The vitrifying calculus is the next most ordinary form of the complaint, so denominated from its running into vitreous globules under the blowpipe. Its composition consists of phosphate of lime, in combination with phosphate of ammonia and magnesia. It much resembles the triple phosphate in colour, and leaves a white dust on the fingers. It is not usually laminated, but is so sometimes, the interstices being studded with sparkling crystals of the triple phosphate. The unlaminated species is often large, spongy, and moulded to the contracted cavity of the bladder. It is easily soluble in acids, and partially in dilute muriatic acid. If the solution of oxalate of ammonia be added, a precipitate of the lime takes place, and the magnesia may be separated by the addition of pure ammonia.

Next in frequency probably is the oxalate of lime, or mulberry calculus. It is more generally found in children than in adults, and is of great weight in proportion to its size, and has usually a number of irregular prominences on its surface, generally of a dark brown or black colour.

All these varieties are subject to alternation, especially in adults, their successive laminæ being manifest on a section of the stone; and there may be sometimes, though rarely, an admixture of these ingredients. The above enumerated descriptions constitute the vast majority of urinary calculi, but there are a few other rare varieties which it is merely necessary to enumerate.

6. The bone earth, or phosphate of lime calculus.

7. The cystic oxide.

8. The carbonate of lime.

9. The santhic oxide. (Dr. Marcet.)

10. The fibrinous calculus.

11. The prostate calculus.

I have witnessed a few specimens of the cystic oxide calculus, of a yellowish white colour, confusedly crystallized throughout their substance. One of these had a beautiful golden metallic lustre.

The causes of these numerous alternations are referable to the nature of the ingesta, to the vicissitudes of temperature, to affections of the nervous system, to hysteria, and occasionally to injuries in the neighbourhood of the kidney producing proximately a deranged condition of the assimilating functions of chemification and chylification, and altering the qualities of the blood.

A hereditary predisposition is frequently manifest in the urinary and neighbouring organs; such tendency is often curiously modified in different individuals of the same family. A parent, for instance, shall have laboured under disease of the kidney or bladder; one of the sons has been cut for the stone, and another has suffered from diseases of the rectum; the daughters have suffered from uterine affections. Indeed it has been frequently remarked that, when the males of a family have been subject to urinary affections, the females have been more or less liable to disease of the generative system. Persons also suffer from different forms of the disease at different periods of life, and this again alternates with diabetes. Lastly, where acids are formed in excess in the kidneys, the urine is commonly small in quantity and high coloured; whereas in neutral or alkaline deposits the urine is pale and increased in quantity, and the diseases are those of irritation and debility. (Prout.)

Calculous affections frequently occur in gouty subjects.

The above circumstances teach us the deep-seated and constitutional nature of urinary diseases generally, their intimate connection with each other, and the important information respecting the nature of any particular disease to be derived from the nature of the urine.

The free use of acids and accecent drinks is considered to be often a cause of that derangement of the digestive organs leading to calculous deposits. The errors in diet of the natives of India, especially in children, who are permitted to devour various kinds of unwholesome acid sweetmeats, and particularly coarse unleavened bread at all hours of the day, are notorious. A late intelligent surgeon (Burnard) attributed to the latter article of food the main cause of the disease in India in the same manner as it has been referred in Norfolk to the coarse dumplings in that county, where the complaint is also so common. The bodies of natives of India are generally exposed to the vicissitudes of heat and

cold in a variable climate, especially in the western provinces (where the disease is far more prevalent than in Bengal). The vicarious office of the kidneys is consequently often called forth. In the moister and more equable climate of Bengal, and where the ordinary diet consists of rice and pulse, instead of the unleavened bread or "auto-cake," there is a marked diminution of the sufferers from this complaint.

The intelligent mother of the European child (No. 69) mentioned that the symptoms of gravel which terminated in stone, ensued after a fit of indigestion produced by his having eaten guava.

One cause of the great frequency of the disease in children may be owing to the comparative smallness of the urethra, so that a nucleus which would be avoided with facility in the adult, would be detained in the bladder in a young subject.

An obvious explanation on the same principle suggests itself for the comparative rareness of the disease in the female.

Stricture of the urethra and enlargement of the central lobe of the prostate gland are a frequent exciting cause of the complaint, especially in adults and old subjects predisposed to the diathesis, owing, partly, to the mechanical obstacle which they present to free evacuation of the contents of the bladder, and partly to the local irritation of these diseases, associated with that general derangement of the constitution which attends the severe forms of these affections. Calculi are sometimes formed around various extraneous bodies which have accidentally found their way into the bladder, as needles or pieces of bougie, &c. Sir A. Cooper relates an instance of a piece of slate-pencil having formed the nucleus of a calculus of the triple phosphate, which is the kind of calculus which forms under great irritation. I met with an instance where a bullet formed the nucleus of a calculus, in the case of Surgeon Pilkington, H.M. 21st Fusiliers, after having passed through the ischiatic notch, and which he related to me whilst witnessing the operation of lithotomy in Fort William.

The great frequency of the disease in India is now well established. The late Mr. Burnard cut about forty patients for stone at the city of Benares. I have had occasion to operate on four patients in one day, all residing in the same village or its immediate neighbourhood, and 108 cases have occurred to myself during my abode in India.

Of the calculi which have been analysed in India, three-fourths have contained a large proportion of lithic acid. The nuclei have mostly consisted of this substance, and lithate of ammonia was also generally detected. Coatings of ammoniac-magnesian phosphate have been rather common. Phosphate of lime in combination with the triple phosphate (fusible) has been found, as well as oxalate of lime and cystic oxide, exhibiting, therefore, a similar proportion of these varieties to what has been ascertained in Europe.

It would appear that lithic acid generally, in combination with ammonia, constitutes the basis of almost all the calculi, and that successive layers continue to be deposited of the same substance, until that high degree of local and constitutional irritation is produced which changes the diathesis and favours the production of the phosphates.

The lithate of ammonia deposition takes place during the intermediate stage. It may be urged, that in the case of all foreign bodies which have occasionally found an entrance into the bladder the phosphates have been deposited upon them. How is this difference accounted for, since the irritation, one would presume, is equal from a nucleus as from a foreign body? Perhaps the irritation is more sudden in the latter, whereas the constitution is more prepared in the former, and, moreover, has already the lithic acid diathesis pervading it in a high degree, which could not be so easily and immediately changed. The peculiar state of the assimilating functions is also to be taken into account.

Opinion of Magendie.—The theory of Magendie and others, that the lithic acid diathesis is more likely to be induced by animal food and such substances as contain a considerable quantity of azote, is not borne out by these cases, for with a very few exceptions these patients seldom or never partook of animal food. None of the Hindoos, and the few Mussulmans but seldom. Yet, on analysis, almost all specimens from Hindoos contained lithic acid and lithate of ammonia. Their diet, with scarcely any exception, has been vegetable and farinaceous. Not but that certain articles of their food are to a certain degree azotified: the gluten of the wheat, the dāl (pulse), and especially the dhace (sweet curds); but this does not invalidate the fact of their diet being by no means of a highly azotic kind. Neither is there any foundation for attributing the supposed rarity of calculi in hot climates to the vegetable food, to which the inhabitants are habituated. The frequency has already been proved, notwithstanding their vegetable diet.

Size and Figure of Calculi.—Calculi are liable to great variety in their size and figure. The largest I have had occasion to remove weighed about four ounces. Instances of very large ones are recorded, even to the extent of forty-four ounces; their extraction has generally been attended with fatal results.

Calculi are usually spherical, oval, or flat. Their number also varies. I have sometimes removed four from the bladder of the same individual. Their surfaces are always smooth from attrition. I once extracted no less than 231 calculi of small size from the interior of the prepuce, in a case of phymosis with complete closure; the calculi were lodged like a parcel of pebbles in a bag, between the glans and the prepuce.

Calculi are occasionally encysted, though fortunately such a circumstance is exceedingly rare. An interesting case occurred to myself, which will be described elsewhere.

The symptoms and means of correcting the different diatheses, in order to prevent the formation of calculus, or its recurrence after an operation, is the next important point for consideration.

The lithic diathesis exhibited in the amorphous sediments is excited in dyspeptic individuals from simple errors in diet, from unusual and unnatural exercise, from cold and damp applied to the feet, and from various and debilitating causes. The deposits are of a yellow-red or pink colour, the lithic acid being combined with ammonia, and sometimes with phosphate of soda in the former—the second consisting essentially of the lithate of ammonia, or lithate of soda, tinged with the colouring matter of the urine, the last of lithate of ammonia without the yellow tint derived from the colouring matter. The crystalline sediments are nearly pure lithic acid. The symptoms attending this diathesis are, more or less, pain or uneasiness in the region of the kidney, with irritation and heat about the urethra and neck of the bladder, and frequent micturition. Children, especially the offspring of gouty and dyspeptic parents, are exceedingly liable to this affection. It frequently occurs in sedentary and luxurious individuals on the decline of life, especially in old Indians who have suffered from hepatic affections and led irregular lives. Organic disease of the right kidney is no uncommon result. European residents in India often induce a fit of the gravel by excess or irregularity, whether as to the quantity, quality, or time of receiving the ingesta. Champagne will produce it in some, claret in others, and beer or other indulgences in others. The remedial indications will be best fulfilled by attention to the *primæ viæ*, by the exhibition of alteratives, laxatives, tonics, and antacids of soda and potash, and in debilitated subjects by the carbonate of ammonia. These alkaline carbonates are best administered in the form of effervescent draughts with an excess of the alkali. Aesculent drinks should be avoided, and exercise enjoined. Diuretics and demulcent drinks will co-operate in carrying off the deposit, and alleviating pain. Turpentine and

squills are often recommended, and sometimes colicium. Hard waters should be particularly avoided. A healthy action of the cutaneous surface should be favoured by the employment of the warm bath. In severe cases anodynes of hyoscyamus and opium should be employed.

The phosphatic diathesis is denoted by the pale colour and usual increase of the urine. It has a great tendency, from slight causes, to deposit the lithic amorphous sediment, intermixed with the phosphates. After standing for a few hours, it is covered with an iridescent pellicle, consisting principally of the triple phosphate of magnesia and ammonia. In warm weather it becomes putrid, assumes a yellowish opaque appearance, and frequently deposits large spicular crystals of the triple phosphate, of a perfectly white shining appearance. The amorphous sediments of the phosphate sometimes contain an intermixture of the phosphate of lime, which is produced from the mucus of the inflamed internal coat of the bladder. The irritability of the system must be allayed, and in severe cases opium will be requisite to allay irritation. When these symptoms have subsided, the opium and hyoscyamus should be combined with the mineral acids, quinine, uva ursi, and other tonics. Hydro-chloric acids of particular service. The use of oranges and lemonade should be freely allowed. The saline aperients should be preferred, plasters to the loins are of advantage, and great attention should be paid to alleviate mental anxiety.

The oxalate of lime diathesis is extremely rare in the form of amorphous or crystalline sediment. It is not unfrequently associated with gout, and, as lithic acid frequently is, with a tendency to cutaneous affections. Professor Brand and Drs. Marcet and Prout consider this variety as generally taking place in individuals of sound constitution, and rarely occurring a second time. Its treatment is similar to that adapted for the lithic acid diathesis, with which it alternates. This form of disorder may be ascertained by the existence of pain in the kidneys, and other symptoms of gravel, without any appearance of gravel itself, by the urine being of a yellow tint and acid, with derangement of stomach and an inflammatory diathesis, either constitutional or local, especially if this be associated with suppressed gout, or cutaneous disease. Its treatment is similar to that of the lithic acid deposit, with which it alternates. The muriatic acid may also be given with advantage to change the diathesis to that of lithic acid.

The other varieties of urinary calculi are very seldom exhibited in the form of amorphous sediments; where they do occur they are treated on precisely similar principles, administering acids where the urine is alkaline, and alkaline carbonates where it is acid.

It is very important to test the various changes which the urine undergoes during the treatment, in order to enable us to regulate the doses of alkaline or acid remedies.

Renal calculi descending down the ureters are usually attended by violent pain in the course of these tubes, nausea and colicky pains, retraction of the testicle, and numbness and pain in the thighs. Instances have been known of their remaining in the pelvis of the kidney, occasioning inflammation and suppuration of that organ; but this circumstance is rare: they may likewise lodge in the ureters and obstruct the passage of urine. Venesection, cupping, and active doses of calomel and antimony should be the remedies employed, with the anodynes of hyoscyamus and opium already mentioned. On the subsidence of the paroxysm the patient should have recourse to the warm bath, warm fomentations, and to the remedies first indicated for the diathesis.

Calculus of the bladder may be recognised by the very acute symptoms which generally accompany it, chiefly during the evacuation of urine, which is very frequently voided, owing to the great irritation caused by the pressure of such a foreign body in contact with the mucous lining of the bladder. The pain is referred to those parts which derive their nerves from the

same source as the bladder, and to the bladder itself. The pain extends along the course of the urethra to the extremity of the penis, and there is often pain in the thighs and loins. There is great variety in the degree of pain, depending upon the irritability of the patient's constitution, on the inequalities of the surface of the stone itself, its position in the bladder, and its size. Sometimes old subjects scarcely experience any pain at all; in others there are considerable intervals of ease. The paroxysms of pain in some are most excruciating. The pain is most severe on the whole of the urine having been voided, when the calculus falls in immediate contact with the neck of the bladder. There is frequently a discharge of mucus of aropy consistence, which is sometimes accompanied with blood; especially after exercise causing the stone to be agitated within the bladder, so that it is impossible for the patient to take any exercise which is attended with jolting, either in a carriage or on horseback. Another very remarkable symptom is, that the patient is constantly rubbing and pulling the glans, with the view probably of deadening the sensation of pain which is referred to that part, the consequence of which is that the prepuce is frequently much elongated, and the whole organ often enlarged. The sufferer frequently forces his fingers up the rectum, and actually tears it during his agony. There is often prociencia of the rectum. Many natives of Hindoostan sit down on the ground and press their heels with great force against the perineum during the paroxysm, and remain in that position. Others roll themselves on the ground, dance round in a circle, or lean on their elbows or the top of their head, with the pelvis raised, in order to cause the stone to fall towards the fundus of the bladder. The flow of urine is often emitted in a full stream, and stops suddenly before the whole is evacuated, owing to the calculus falling on the cervix vesicæ: it again flows on change of position. There is often a great deal of straining and bearing down. Sympathetic pains extend to the testicle, to the back of the thigh, and to the hollow of one or both feet, with a burning sensation at the soles of the feet.

Sounding.—The symptoms are in many respects so pathognomonic that there can seldom be any difficulty in the diagnosis, nevertheless there are instances where some of these marked symptoms are not manifest, where the calculus is smooth, perhaps encysted, and the idiosyncrasy of the individual not irritable; it therefore becomes, in such instances, requisite to introduce a metallic instrument, which may strike the calculus, and communicate to the touch and to the ear a sound which immediately detects the existence of a foreign body. Again, there are instances of irritability in children from gravel, which simulate the stone, and which subside on the exhibition of mercurial purgatives, followed by a few doses of rhubarb and magnesia. But the operation of "sounding" should only be resorted to on these dubious occasions; for it is extremely painful in the irritable state attending calculus, and only aggravates the sufferings and excites the alarm of the patient; circumstances which are most unfavourable, previous to the patient undergoing the necessary operation for the radical cure of the disease, who requires to be soothed both mentally and bodily, whereby he is in a much better state of preparation to undergo so serious an operation. Cases are on record where patients have died solely from the irritation and inflammation excited by sounding, and there are many more not on record. In ordinary cases, the introduction of all instruments should be reserved until the moment of operation, when every prudent surgeon must then distinctly ascertain the presence of the stone, however clear the symptoms may have been; for operations have unfortunately been undertaken where no stone has been found. It is to be feared that this has arisen from the rashness and precipitancy of some surgeons desirous of operating. The instrument should have a curvature of the diameter of a smaller circle than

that ordinarily given to sounds; it ought to be large and smooth. It should be a quarter of a circle whose diameter is three inches. Where there is fluid in the bladder the calculus will be found at the lower part of the viscus, which will vary according to the posture of the patient. He should be first sounded in the horizontal position, reclining on his back. The instrument should be introduced completely, then partially withdrawn; the handle raised, directed laterally, and moved in various directions in search of the stone, which may be so small as to elude the point of the instrument. The projection of the inferior part of the prostate sometimes forms an obstacle by raising the point of the sound, the stone being lodged behind it, and escaping detection. The pelvis may then be raised so as to cause the fundus of the bladder to become the most depending part, the stone thus shifting its position. The utmost gentleness should be used, consistent with the most minute exploring. A dexterous employment of the instrument will enable us to ascertain, with tolerable accuracy, not only the size, but also whether there be a plurality of stones, measuring the stone as it wore upwards, inferiorly, and laterally, with the extremity of the instrument. It is erroneous to suppose that the dimensions of calculi cannot be ascertained by examination through the rectum. The natives of India have from time immemorial been in the habit of bringing down the calculus by pressure above the pubic region, moulding, as it were, the hypogastrium, and causing the stone to descend towards the outlet of the pelvis; with two fingers in the rectum they then not only seize the stone but cause it to bulge in the perineum. This I have myself witnessed.

Calculi of small dimensions can be extracted by means of Weiss's forceps. The instrument is made of different sizes, and consists of two blades. It is introduced in the usual manner, and, on its reaching the stone, the blades are expanded, the convex part being pressed downwards. The blades are now permitted to close slowly, and the calculus is embraced. When the urethra is large, I have known a calculus to be brought away of the size of a filbert. The presence of the calculus between the blades of the forceps is ascertained by pushing the wire through the canula, when if it goes home the calculus is not there, and the manipulation must be repeated. The instrument must be withdrawn with great care and gentleness. It can be used both safely and successfully with care, and thus the necessity of a more serious operation will be obviated. Sir Benjamin Brodie's modification of the instrument is furnished with a silver spout, through which the urine may flow to facilitate the entrance of calculi between the blades as the water is flowing through.—Fig. 1.

Smaller Calculi, how to be got rid of.—Calculi which are not of greater diameter than that of the urethra are generally carried away through that passage by the impulse of the stream of urine. Enlargement of the prostate, however, will prevent this, by acting as a valve, so that extremely small stones may be retained in the bladder. Thus individuals who have long been subject to the formation of renal calculi are, in advanced life, no longer capable of evacuating them, and they become lodged in the bladder. Sometimes these calculi can be got rid of by directing the patient to bend considerably forwards, when evacuating his urine, so as to render the anterior part of the bladder the most dependent.

Dilatation.—We may sometimes effect the extraction of calculi which are considerably larger than the urethra by dilatation. Indeed stones of

extraordinary size have been got rid of in this manner. On one occasion I employed dilatation to a considerable extent by the largest sized sounds, and by the calculeo-fractor of L'Estrange, intending to crush the calculus. The patient suffered all the more distressing symptoms attending the presence of a stone in the bladder, which had been distinctly detected by sounding. The consequence of this dilatation was, that a stone nearly an inch in its long diameter, and the third of an inch in its shorter diameter, was brought away, and the patient escaped the necessity of an operation for its extraction from the bladder.

Dilatation, and Incision in the Perineum.—From the knowledge of the great dilatability which the neck of the bladder is capable of undergoing, stones which can be brought through this part and into the perineum by Weiss's forceps, though too large to be advanced further along the urethra, may be out down upon and extracted. Stones an inch in diameter have been got rid of in this manner by a simple operation seldom attended with serious results.

Dilatation may be accomplished in the following manner. Introduce a metallic bougie or sound of such dimensions as the urethra will admit without inducing inflammation. Let this be repeated, every day or every second day, according to circumstances, substituting each time one of larger size, thus dilating the urethra, until it is a good deal larger than its natural size. When this has been accomplished as far as practicable, let the patient drink copiously of diuretics and diluting drinks—the spirit of nitre or the compound spirit of juniper. The patient should retain his urine as long as possible, and, when he can no longer resist, the calculus may be carried along the dilated passage by the stream.

Should the above method be unsuccessful, we may facilitate the exit of the stone by the following plan. Introduce daily into the urethra and bladder a large bougie, and let it remain there. Let the patient drink freely of diluents, in order that the bladder may become distended, and when the patient is compelled to expel the urine, let him lean forward and suddenly withdraw the bougie. Stones which have for months lodged in the bladder may thus be extricated.

Method of using Weiss's Forceps.—When it becomes necessary to extract calculi from the bladder by means of the forceps, this viscus should always contain a moderate quantity of water. Should the patient have voided his urine, tepid water may be injected by means of a catheter. The position of the stone should first be ascertained by means of a sound. The forceps, previously warmed and oiled, should then be introduced, and directed towards the calculus, and when the forceps are felt resting on it, let the blades be cautiously opened, and the surgeon endeavour to seize it. Numbers of stones may in this manner be extracted. Sir Astley Cooper has removed as many as eight from the same individual.

Calculi in the urethra are found in various situations, causing obstruction or retention of urine. They can seldom be extracted with the forceps, because, on endeavouring to bring the forceps forward, the urethra is pulled back upon the stone, the mucous membrane is often lacerated, and the stone is not moved. They are generally found in the membranous portion in the perineum opposite the scrotum, or corresponding with the situation of the frenum. The treatment consists in prescribing opium, the warm bath, and fomentations. The mechanical measures consist in passing a large bougie down to the stone, taking great care not to press it against the stone, lest it should be forced into the bladder. The bougie must be tied to the urethra, and the patient prohibited from voiding urine until that fluid has accumulated, and the urgency is so great that the patient can no longer resist. The bougie is then to be detached and withdrawn, and the force of the current of accumulated urine will generally be effectual in shifting the position of the stone. Should this

be ineffectual, the calculus is to be grasped with the fingers, and cut down upon by a free incision. If lodged posteriorly in the membranous portion, they are to be cut down upon by an incision on the left side of the perineum. When the calculus is lodged opposite the scrotum, there is danger of the urethra bursting and extravasation taking place into the cellular tissue; the stone must then be pushed back from its position towards the perineum, and the same efforts made towards its removal as on the former occasion. If it is found impossible to remove it, or if it returns to the point and is again impeded, a free incision must be made, so that the urine may pass with greater freedom, and the calculus be taken out. Calculi opposite the frenum are to be removed by a bent probe, or the urethra may be enlarged by incision. When calculi are fixed behind strictures, and the symptoms are urgent, it will be necessary to cut down upon the stricture opposite the raphe, as recommended for retention of urine arising from the latter disease, laying the parts freely open, and advancing the finger towards the neck of the bladder.

Urinary calculi beyond the dimensions of an inch in diameter, when lodged in the cavity of the bladder, can only be removed by lithotomy or lithotripsy.

Lithotomy by the Lateral Operation.—The primary circumstance for consideration is the state of the patient's constitution. The preparatory treatment, therefore, first presents itself to our notice. In most cases a vegetable diet for a few days, the administration of a saline purgative, and attention to the peculiar diathesis already fully referred to, is all that is requisite, and will generally succeed in alleviating constitutional and local irritation. It must always be remembered, however, that the presence of a foreign body is the source of irritation, and that the sooner this is removed the better. In the natives of India their systems are habitually prepared for operation, and the little advantage derivable from preparatory treatment is more than counterbalanced by fear and suspense. They come with confidence in the superiority of European skill, from hearing of our success on other sufferers, and they seek for speedy relief from agonizing pain. The patient is infinitely more pleased by immediate operation, which, when set about with the least possible ceremony, is not looked upon at all seriously by him; indeed, if the surgeon does not operate at once, but irritates and alarms him by the use of sounds, the patient almost invariably loses all confidence and leaves him. Speedy operation particularly refers to the lithic diathesis—a form of the disease the most common, and accompanied with very little constitutional irritation, excepting that which depends on the great degree of local irritation and pain of the disorder. To children, likewise, these principles still more uniformly apply.

I have often observed, after the frequent administration of the sulphate of magnesia, that the calculus has externally a recent and beautiful superficial crystallized coating of the triple phosphate, showing how certain salts which are known to appear very speedily in the urine can be made to predominate and soon to change the diathesis.

(To be continued.)

CLINICAL NOTES.

No. VI.

By RICHARD DE GUMBLETON DAUNT, Esq., M.D. (Edin.), Member of the Faculty of Physicians of Rio Janeiro, and Member of, and late Honorary Secretary to, the Parisian Medical Society.

To Doctor Antony Joseph Peixoto, a Brazilian surgeon practising in Rio de Janeiro, and graduate of the Faculty of Medicine of Paris, humanity owes the blessing which it has this year received in the scientific verification of the virtues of guano, as a means of cure of perhaps the most frightful scourge of the whole of known maladies—the lepra leonina, or tubercular elephantiasis of the Greeks, the leprosy of middle-age Europe. This disease, now historical in

Europe, except in a few rare instances in the extreme north, devastates whole populations in Brazil, principally in certain districts of the provinces of Minas Geraes and San Paulo; and not alone is to be viewed with all the dread inspired by a disease so loathsome and so disgusting to the human form, and so ruinous to the development of the material progress of the nation from the check it gives to population, but also, and chiefly, with millionfold abhorrence on account of the deplorable moral depravation it causes in its victims, who are no sooner lazar than they appear to be suddenly brutalized and subjected to the dominion of the grossest animal instincts, and also imbued with a hatred of their race and a desire to reduce others to their own condition. Unfortunately the presence of indigent lazars is tolerated in many districts, where they appear in the public streets, and mix with the healthy population; so that the evil is still greater than it would be were the laws rigidly enforced which oblige these unfortunates to remain within the walls of the leper hospitals. With such a state of things, it will be conceded that it is impossible to exaggerate the satisfaction which all should entertain on knowing that already the power of guano over this disease has been tested by the perfect cure of several cases, in the hands of Dr. Peixoto, who was led to make experiments with this substance from knowing that, already in Peru, the chance residence for some time of a leper in a guano island had been succeeded by his perfect cure. Dr. Peixoto commenced his experiments at the beginning of this year, and at the end of six months had the gratification of witnessing the first cures obtained by art over this horrible disease. The guano hitherto employed has been American; and, while Dr. Peixoto gives internally the ammoniacal salts it contains, its chief mode of application, and that which in my opinion is the only efficacious, is the formation of an atmosphere highly charged with guano exhalations—as, *verbi gratia*, the leaving guano scattered on the floor of the apartment, the use of mattresses stuffed with guano, baths containing this substance, &c. It appears that none of the inconvenient physiological effects which guano is accused of producing on the crews of guano vessels have been found to appear in those who have undergone this treatment. About two hundredweight of guano are used in the treatment of each leper, when treated isolatedly; and six months appears to be the space of time in which a cure may be hoped for. It is said that, when the disease is decidedly hereditary, the efficacy of guano is much less—a fact to be kept in memory by all investigators, who should, in their first trials of guano, shun these cases. May we not presume that it is in such that the alteration of the nervous centres, noticed by Dr. Faivre, precedes the dermal development of the disease? Hence the difference in the power of guano over the several cases. I have not the means of describing at length the disease, or its pathology, but will confine myself to stating that the earliest indications of its presence are a thickening of the skin of the face, a coarser expression of features, a greatly increased development and injection of the capillaries of the face, a baldness of the eyebrows, and a want of sensibility in certain parts of the body, generally in small scattered points.

The class most liable to this disease are, not the slaves nor the higher orders (though it has its victims also among both these), but the free poor population—a race of mixed origin, part Portuguese and part Indian, which exists under the worst possible hygienic conditions. From a mistaken love of independence, and a too easily contented spirit, this class will not exert itself to labour beyond a degree necessary to avert starvation. Living a life of indolence in wretched habitations, its chief aliment, in the districts where leprosy is chiefly endemic, is the farina obtained by grinding the nuclei of the turio of a species of pine which forms large forests in these districts, and which flour appears not dissimilar to that of the acorn; the flour of the Indian corn made into a parrich, like that made with oaten

flour in Scotland; and such animals as the chase yields them, with, when they are somewhat more thrifty, pork. This uniform and ill-chosen diet enters, doubtless, for a large share in the casualty of the disease; and the reckless way in which this class continues to associate with those already affected is a still more efficient means of spreading it. It may, also, be remarked that in many districts goitre and cretinism are endemic, together with the Grecian elephantiasis, or tubercular leprosy. As this disease is also endemic in the interesting and valuable colony of the Cape of Good Hope, where two leper hospitals exist, it is to be hoped that the English Government will depart from its usual apathy in all measures of public benefit, especially where the public health and the interests of the medical sciences are concerned, so far as to direct a full trial to be made of the guano by the medical officers of those institutions. Before concluding my statement it is well to add, that though Dr. Peixoto's success has not yet, for want of time, received a universal verification; he is a man of so high a grade in his profession that the most implicit reliance may be placed in every word he has published on this matter. Dr. Peixoto, as an operating surgeon, is, I believe, now, by the demise of the provincial surgeon, Francis Alvares, entitled to be called the most dexterous in Brazil.

The form I have given to these occasional papers relieves me from the necessity of making each a formal dissertation, and enables me to pass from one matter to another without incurring the charge of confusion; and of this privilege I now avail myself. It will be recollected, that some years back much was written of the effects of indigo in epilepsy; I believe it was chiefly tried in Northern Germany, for I am not aware of its ever having been much accredited in England or Ireland; and I remember to have heard Andral, while I attended his lectures, speak of it as equally uncertain with other boasted anti-epileptics. I had long been desirous of giving indigo a trial, when, nine months ago, I was asked to treat an African female slave, who had been, since a child, subject to epileptic fits. Her age was about thirty, and the epilepsy appeared purely idiopathic—at least I could detect no lesion of which it could be symptomatic. The fits were violent and frequent, generally two, and often four or five, daily; and she was much reduced in strength. I judged this a fair case for testing the powers of indigo, and, having first given a purge of turpentine, to satisfy myself that intestinal worms were not the cause, I commenced the exhibition of indigo, of which ten grains were given three times a day, united with a few grains of aromatic powder. In three weeks a decided amelioration was visible, and in a short time the fits ceased to appear oftener than once monthly. I obliged her to continue the use of the indigo for six months, when she presented an appearance of perfect health, and, having passed the last two months without a fit, I thought it needless to pursue the treatment further. I think it probable that the fits will at times recur in this patient; but, allowing that three or four times annually this should happen, considering the wide difference between such a state and that in which for many years she had been, and was in when I prescribed for her, I think I am fully justified in making public the case, as an encouragement to a more patient and multiplied use of indigo in idiopathic cases (viz., those connected with a faulty dynamisation or perverted mode of action of the nervous system) of epilepsy.

I lately had an instance of the value of fuligokali (which I mention as an incitement to its more general employment), in the cure of an impetiginous eruption of five or six years' duration, and covering the greater part of the body; by the application, during two months, of an ointment of fuligokali, of the strength of 3ss., and afterwards of $\mathcal{O}j.$, to the ounce of axunge, the annoying itching, which occurred nightly, was relieved by it in the first week of its use.

City of Campinas, Province of San Paulo, Brazil, Oct., 1846.

OBSERVATIONS ON THE BEAD SUTURE.

By CHAS. BROOKE, F.R.S., Surgeon to the Metropolitan Free Hospital.

[To the Editor of the Medical Times.]

SIR,—As the question, what mode of suture is capable of holding separated parts in apposition with the minimum of irritation, is one of some importance in surgery, especially as regards the issue of all plastic operations, I trust the following reply to some remarks, contained in a lecture delivered by Professor Fergusson, and published in your last number, may not be deemed unworthy of a place in your valuable periodical.

I have the honour to be, Sir,

Your obedient servant,

Keppel-street, March 15.

CHAS. BROOKE.

After mentioning the common knot and its known inefficiency, the surgeon's knot, Sir P. Crampton's method, and my bead suture, Mr. Fergusson remarks:—"The common knot and the surgeon's I have used most frequently, for I have always supposed that the beads might increase the after irritation;" and after describing a knot, which will probably be more familiar, as being identical with the *Byron tie*, he further adds—"I advise you to think of this plan, which seems to me to embody the advantages of the beads, while the knots will from their size be less annoying to the patient, than the materials alluded to."

The best reply I can offer to the first remark is, that I have now had sufficiently ample experience in the application of the bead suture, not only to the common integument, but to the mucous surfaces of the palate and vagina (the details of which will shortly be made public), to warrant the statement that the beads not only do not increase the after irritation, as Mr. Fergusson has "always supposed," but, on the contrary, that they produce no sensible amount of irritation.

To the second remark, in which the slip knot is recommended as *seeming* "to embody the advantages of the beads," I must reply a little more at length. The bead suture (a description of which will be found in page 84 of the Abstracts of Communications, in the Report of the British Association for 1845) differs from all the other modes referred to in the lecture in this important point, namely, that the threads are not brought together over the wound (in which respect it resembles the old quill suture), and, consequently, the included portions of the edges, not being encircled or constricted by the ligature, are left free to undergo that degree of tumefaction which must necessarily precede the effusion of coagulable lymph, and the subsequent phases of the process of adhesive inflammation.

But this is not the only, or even perhaps the principal, advantage of the bead suture. It has been truly remarked; in the very instructive lecture on Staphylophary, that "hitherto the principal cause of failure has probably been the dragging on the stitches, from the action of the muscles, and the consequent disposition of the parts to be drawn asunder": and no doubt the ingenious device of Professor Fergusson will greatly obviate this inconvenience, but will not supersede the adoption of any subsequent measures which may be shown to be desirable.

It must be borne in mind, that in all the other modes of suture alluded to in the lecture the pressure arising from traction acts principally on the cellular tissue through which the thread passes, and on a surface equal only to the diameter of the thread; whereas in the bead suture the pressure is sustained by the mucous surface, and by a portion of it equal in extent to the opposed surface of the bend, the form of which is an oblate or flattened spheroid, the length of the axis not being more than half the transverse diameter.

The giving way of any suture manifestly depends partly on the yielding of the fibres to the mechanical force of pressure, and partly

owing to their removal by absorption or suppurative inflammation under the influence of the pressure, if it be not too forcible; and, as the vital yielding of soft parts will bear some proportion to the amount of pressure upon them, when a diminished pressure can be shown to exist, less tendency to irritation and ulceration may reasonably be inferred.

The capability of the bead suture in sustaining mechanical pressure, compared with that of any suture on which the soft parts are included in a loop, may be readily tested by the following experiment. Let an incision be made in any portion, either of the external or mucous surface in the dead subject; let two portions of the same ligature be passed through two similar parts of the cut edge, taking up as much as would be ordinarily taken up in a suture; let one of these be doubled by bringing the two ends together, and let the external end of the other be passed through a flat bead, and prevented by a knot from returning. If the two are now gradually but forcibly torn out in succession, the difference in the amounts of force necessary to effect this object will be immediately apparent.

Unless, therefore, Professor Fergusson is prepared to argue that any given amount of pressure concentrated on a very small space is not diminished in intensity when diffused over a comparatively large one, I must beg of him, in candour, to suspend the weight justly due to any opinion he may deliver *ex cathedra*, until he has either made trial of the bead suture himself, or ascertained the results of its efficient application, either by myself, or by any other surgeon who will take the trouble of acquiring, by a little necessary practice, the manipulation of my instruments.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF SCIENCES.

Meeting of March 8; M. BIGNONIART in the Chair.

ETHEREAL INHALATIONS.

The following melancholy case was related by Professor Roux:—

At the beginning of the month of March a man was brought into the professor's ward, at the Hôtel Dieu; he was affected with a wound of the scrotum, which had occasioned tetanus. Although it appeared evident that he would not live beyond thirty-six, or at most forty-eight, hours, still the hope was entertained of diminishing the violence of convulsions by the inspiration of ether. After a few minutes the subject became insensible, but half an hour after the experiment he expired: he would have died even if not submitted to the process; but M. Roux thought it his duty to say that, undoubtedly, death would have occurred in this case much earlier than if inhalation had not been performed.

DETECTION OF SIMULATED DISEASE BY ETHER.

The two following cases were forwarded by M. Baudens, Surgeon-in-Chief of the Military Hospital of the Val-de-Grâce:—

1. A soldier of the 25th Light Infantry had been eighteen months in the service; when he joined his regiment he presented a most striking spinal distortion; the ingenuity of several "conseils de révision" had, in this case—notwithstanding many trials, completely failed in detecting any imposition: the truth was revealed by the inhalation of ether. The soldier was placed on a table, lying on his back, and the incurvation was so considerable that the lumbar region alone bore upon the table. After four minutes' inhalation, unconsciousness was produced, and the head, shoulders, neck, and back were involuntarily restored to their natural rectitude.

2. A young soldier entered, on the 1st of March, the Hospital of Val-de-Grâce, with an

ankylosis of the hip-joint, which M. Baudens had some reason to believe was simulated. Inhalation was resorted to, insensibility produced after eight minutes, and muscular relaxation in twelve; but the thigh remained immovable, and when raised, its movements were evidently and directly communicated to the entire pelvis.

DR. BOUCHUT.—SIGNS OF DEATH.—On the 22nd of February, a paper on this subject was read by Dr. Mandl, in which that gentleman stated that vesication by the application of heat was a certain sign which might serve to distinguish real from apparent death. M. Bouchut states that Dr. Mandl's opinion, which had already been professed by Prévot (of Padua), Louis, Duncan, Christison, Orfila, and Devergie, is one which Magendie and Leuret's experiments tend to disprove; and which experiments, altogether his own, and witnessed by Messrs. Andral and Rayer, also showed to be erroneous. In conclusion, Dr. Bouchut asserted that eight, twelve, and twenty-four hours after death, a blister may still be raised, though not constantly; the facility of its production depended upon the fineness of the skin, the absence of hairs, the quantity of blood and serum infiltrated, and the declivity of the part. Besides, it should be recollected, that vesication did not invariably follow superficial burns in living bodies. M. Bouchut was of opinion that the formation of erythematous redness around burns (a fact already mentioned by Christison) was far more valuable in the diagnosis of real from apparent death, than the formation of a blister. But, although the erythema was impossible after death; it did not follow that it constantly appeared during life, particularly in those extraordinary cases of apparent death in which the capillary circulation is so much modified. Dr. Bouchut was also of opinion that a sufficiently prolonged auscultation of the chest was absolutely indispensable, and would furnish the most certain signs of the persistency of life, or of the reality of death.

ACADEMY OF MEDICINE.

Meeting of March 9; M. BEGIN in the Chair.

ELECTION OF A MEMBER OF THE ACADEMY.—(Section of Therapeutics.)—The candidates were Messrs. Gibert, Trouseau, Sandras, Martinet, Bayle, and Legroux. M. Gibert was elected by a majority of one.

ETHEREAL INHALATIONS.—M. Bouvier related a case of labour in which ether had been employed, and in which the uterine contractions had been arrested by the inhalation.

FACULTY OF MEDICINE.

LECTURE ON GENERAL PATHOLOGY, BY PROFESSOR ANDRAL.

The seat of the morbid element by which disease is constituted may be sought for in three different parts of the system: 1, in the alterations of nervous influence; 2, in the changes of the blood; 3, in the changes which have supervened in those substances which emanate from the blood. In these three great groups many subdivisions should be introduced; and all diseases may either naturally, or with a little allowable hypothesis, be referred to one or the other order. Practically, however, we do not consider this classification applicable, and we prefer the following:—

We recognise fourteen great classes of diseases, viz.: 1, pyrexia; 2, hyperemia; 3, phlegmasia; 4, anæmia, or hypohæmia; 5, hemorrhage; 6, fluxus; 7, dropsy; 8, pneumatosis; 9, alterations of nutrition, or trophopathies; 10, gangrene; 11, traumatic diseases; 12, hæmopathies; 13, alterations of secreted fluids, or crinopathies; 14, neuropathies.

A few words on each.

1. *Pyrexia*.—In this class the increase of temperature of the body is the only constant symptom; and pyrexia are also characterized by the fact that it is impossible to trace them to any alteration of solid textures. When such alteration appears during the

progress of fever, they are caused by the same morbid influence which first occasioned the febrile excitement. They are specially observed on the skin and mucous membranes, and consist in congestion, inflammation, or hemorrhage—either interstitial in the shape of patches and ecchymosis, or discharged from the affected surface; fluxes, as in cholera, miliaria, &c., are also observed. In each pyrexia the local alterations not only may have a special form, but seem to affect a special seat; the cellular tissue sometimes; the lymphatic glands in syphilis; in other diseases the salivary glands; gangrenous inflammation of the cellular tissue and skin in the plague. The blood may be altered in its composition in pyrexia, and this alteration is always the same, consisting in a diminution of its natural amount of fibrine. In many pyrexia: a virus or poison exists in the system.

Pyrexia: are continuous or intermittent, hence a natural division into two orders: in the first we must form numerous genera, and amongst these we may name synocha, inflammatory fever, typhoid fever, miliaria, typhus, gastritis, yellow fever, the plague, varicella, rubella, scarlatina, cholera, acute farcy, and carbuncular fever. These various maladies are connected with each other by their essential characters, and some arise spontaneously; others are developed by contagion or infection; and several are special to particular latitudes.

The second order is constituted by intermittent pyrexia, in some of which no other morbid phenomenon, besides the febrile excitement, can be detected; in others the febrile paroxysms are attended with various accidents, much the same as those which may be observed during the progress of continuous fever: fluxes, for instance, or losses of heat (which have not, however, been thermometrically proved), but which have been known to cause death, as in the algid fever; hence a subdivision of intermittent fevers into benignant and pernicious. Cullen perfectly understood the connections between the two orders of pyrexia, so much so that as a type, in his description of fever, that illustrious author takes the paroxysm of ague. In the various parts of the globe, according to the intensity of the producing cause, of the different degrees of atmospheric heat, of the presence of marshes in mild or hot climates, we can observe the gradual transformation of intermittent into continuous fever, and reciprocally. They are different types of the same disease; but, like intermittent or continuous neuralgia, they are still the same malady.

Elevation of temperature is the only constant phenomenon which observation proves to exist in fever. Entering the field of hypothesis, may we not suppose this increase of heat to be the result of a more active combustion produced in the system by a temporary arrest of the nutritive movement? The removal from the system of a large quantity of nitrogen with the urine during fever, the production of an increased amount of water, carbonic acid, and bile in the same condition, for the separation of superabundant carbon and hydrogen, would seem to confirm our supposition. This arrest of the nutritive movement can occasionally be referred to the interference of a deleterious agent, external or internal, by which the vital properties are more or less interfered with, and the activity of nutrition slackened; or it may be attributed to an inflammation which calls to a limited part of the body an accumulation of blood, producing new secretions, a new mode of nutrition, a new and morbid elaboration of the elements of the blood; under the influence of a similar process, it is not impossible to admit that the general nutritive movement may be suspended, or at least rendered less active. All this is doubtless hypothetical; but a time comes when the mind, wearied with the dryness of the mere observation of facts, cannot resist the impulses of imagination; and such speculations, far from weakening its powers, serve, on the contrary, to enlarge its scope and to renovate its vigour.

2. *Hyperemia* is constituted by the accumu-

tion of the blood in a part, due to the arrest or the diminution of the speed of its circulation; hyperemia is always attended with redness, sometimes with tumefaction; the serum of the blood, containing some albumen but never any fibrine, may be extravasated during congestion. According to the nature of its causes, we divide this class into three orders: hyperemia due to increased excitability; hyperemia due to diminution of the powers of circulation; and hyperemia referrible to mechanical causes, impeding the return of venous blood to the heart.

3. *Phlegmasia*.—When congestion has been gradually transformed into phlegmasia, as the disease no longer remains limited to its solid seat: the blood is modified in its composition, and one of its constituent elements, fibrine, is increased in quantity. This latter circumstance is invariably connected with phlegmasia, when they are accompanied with febrile excitement; and yet fever alone will not produce it. We have never met with increase of fibrine in pyrexia. In most cases it is the first order of hyperemia which passes into inflammation, but the two others may also terminate in a similar manner.

4. *Anemia, or Hypohemia*.—This class refers only to local anemia, a disease observed only in a small number of organs—the brain and gastric mucous membrane, for instance.

5. *Hemorrhage*.—Of this class we will say nothing, having on a former occasion treated the subject in *extenso*. Hemorrhages may, like congestions, be divided according to their cause.

6. *Fluxes* are in most cases the result of appreciable organic alterations; in others, on the contrary, the discharge is the only pathological fact which can be detected. They are characterized by the similarity of the fluid secreted with that of the fluid eliminated during health by the same organ. Fluxes have, according to their seat, been divided into three orders:—1, fluxes of the skin, 2, of the mucous membranes; in this order some authors place cholera, and not without some good reasons; we prefer, however, classing that disease with pyrexia. 3. Fluxes of glandular organs, primary or consecutive to congestion or phlegmasia.

7. *Dropsies*.—We mentioned on another occasion that all dropsies might be referred to one of two causes: an obstacle to the circulation of the blood, or a change in its composition. Dropsy in no case can, therefore, be considered as a primary fact—as anything but a symptom; but it is a symptom of such magnitude—it is a secondary fact of such immense practical importance—that we consider ourselves fully justified in forming for it a special class.

8. *Pneumatosis*.—In this class are placed all the gaseous accumulations within the cavities of our organs. We have reason to suppose that gases may even exist in the blood, and, whatever be their origin, they occasion symptoms and diseases which must have a place in all classifications.

We now come to the consideration of other diseases, in which the alterations of the solids is the primary pathological fact:—

9. *Trophopathies, or Diseases of Nutrition*.—These may be congenital or acquired; hypertrophy, atrophy, softening and accidental productions (subdivided into homologous, heterologous, and parasitical), and the various genera of acquired trophopathies.

10. *Gangrene* is in itself a disease which may be brought on by many causes besides congestion and inflammation. It may be produced by an obstacle to capillary or arterial circulation—by the introduction of miasmata or morbid poisons into the system, as in the plague. It is, therefore, something more than a termination of inflammation, and deserves to be separately studied in a class peculiar to itself.

11. *Traumatic affections* form, with the two preceding, the group of diseases in which alteration of the solids is primary.

12. *Hemopathies, or Diseases of the Blood*.—The first order contains the diseases resulting from changes of proportion of the natural elements

of the blood, and in this order we find four genera:—The first of which refers to changes of proportion of the globules, which may be increased as in plethora, or diminished as in accidental or spontaneous anemia. In the second genus we place the changes of proportion of the fibrine—increased in inflammations attended with fever; diminished, on the contrary, and its diminution being a primary morbid fact, from which the other phenomena of disease may be derived—as in scurvy, or purpura;—or this diminution being, as in pyrexia, not a cause but one of the possible results of the malady. In the third genus of the first order we place changes of proportion of the albumen in the blood; increase of the albumen has not hitherto been ever observed: its diminution is constant in one variety of dropsy. The fourth contains the changes of quantity noticed in the saline elements of the blood—a subject which has hitherto yielded to investigation only results of a negative nature.

The second order of hemopathies refers to diseases resulting from the introduction into the blood of principles not habitually contained in that fluid. This order is subdivided into three genera. The first, that in which the elements of our various secretions are found in the blood—for instance, tetanus; diabetes mellitus will probably, at a future day, be classed here. The second genus, that in which morbid products—like pus—are introduced into the blood. The third, in which it contains toxic principles, which may be modified in its constitution, or not changed in any appreciable manner. Here we must place diseases resulting from the passage into the blood of venous miasmata, virus of various sorts (rabies, syphilis, &c.), or even of mineral poisons, such as mercurial or saturnine emanations.

The third order of hemopathies is consecrated to asphyxia, in which, under the influence of various causes, the blood receives no oxygen, or an insufficient quantity of that gas.

13. *Alterations of secreted fluids* are mostly the results of other maladies; sometimes, however, they can be traced to no organic alteration whatever. Calculous affections of the bladder, kidney, and liver belong to this class, in which we must also place, for the present at least, diabetes mellitus. Albuminuria, when not connected with organic diseases of the kidneys, also should be classed here.

14. *Neuropathies* are primary disturbances of nervous action. They may be subdivided into the modifications of intellect, of sensibility, of motility, and of that nervous power which presides over the accomplishment of the functions of organic life.

Such, at the present day, is the most complete classification of diseases. This grouping into classes we have already said to be indispensable to the science of diagnosis, and to that of therapeutics.

D. M'CARTHY, M.D.P.

Great Britain and Ireland.

PHYSIOLOGY.—ON THE LAW OF THE MORPHOLOGY OF THE TEXTURES OF THE HUMAN BODY.

By Dr. ADDISON.

(Continued from p. 38.)

The process of nutrition, as ascertained both by observation and experiment, comprises three intelligible and visible stages:—1, the separation of the colourless cells and protoplasma of the blood from the red current; 2, the metamorphoses of these colourless elements in their progress through the walls of these vessels; and 3, the ultimate product which constitutes the permanent form of textural type. The first stage takes place within the vessels, along their interior boundary; the second takes place in, and gives the forms of, the elements of the walls of the vessels; and the third, or ultimate product, appears at the outer margin, and is in fact an extension, of the vascular wall.

Inflammation.—When the growth and nutrition of a texture of any kind, whether animal or vegetable, is normal, its elements are reproduced or multiplied, its form evolved, and its characteristic qualities and secretions established by a metamorphosis of the nutritive elements, supplied from without, in accordance with the law originally in force in the primary conformation of the parent organism from which it sprung. Every change, every metamorphosis, every action, and every product, yielding or conforming to the law, is an integral element of the complex phenomenon termed health; and every action or product deviating from it is an element of disease.

We have seen that any irritation of a vascular texture is productive of an increased amount of nutritive matter, which is deposited from the circulating blood, upon the walls or inner boundary of the vessels. The increased amount of matter so deposited is a deviation from the law of the texture, and therefore a phenomenon of disease; but the sensible or visible effects upon the texture depend upon the times, stages, and forms of the subsequent morphology, which may conform to the law of the texture, or deviate from it. For example—the fibrous textures are not secreting textures; they do not evolve a viscid mucus mixed with cells; this is not the law of their nutrition. These textures are, therefore, on this account, called serous textures. But there are other textures that do evolve a viscid mucus, mixed with numerous colourless cells, and these are, therefore, termed mucous textures. Now, an unusual amount of nutritive matter deposited upon the walls of the blood-vessels of a fibrous texture, and a conformable morphology, necessarily give rise to an increased amount of the elements of the texture; which becomes thickened by abnormal fibres; and, if adhesions are contracted between contiguous surfaces, it is by fibres; and the serous fluid, which naturally lubricates the texture, is increased in quantity. On the other hand, an unusual amount of nutritive matter, deposited upon the walls of the nutrient vessels of a mucous texture, and a conformable morphology, give rise to an increased quantity of mucus, mixed with a larger number of colourless cells. In either case, an unconformable morphology would produce different forms and qualities—fibrous forms, for instance, upon the mucous texture, and corpuscular forms upon the fibrous textures. If so complex a subject as normal and abnormal nutrition, of conservative and destructive inflammation, be susceptible of a short definition, it may be said, that simple healthy inflammation consists of an increased amount of protoplasma with a conformable morphology; and destructive unhealthy inflammation, of an increased amount of protoplasma, with an unconformable morphology.—*Provincial Medical and Surgical Journal*.

The Placenta.—The human placenta (according to M. Ernest Henri Weber) differs from that of the bitch:—1, the dense network of vessels which conveys the maternal blood, and traverses the entire placenta, consists in the human female of tubes of a much larger diameter, but with thinner walls; 2, the other constituent part of the placenta, the villousities of the chorion, which convey the fine network of embryonic capillaries, form in the bitch membranes and folds, and in the human species ramifications, which terminate in fine threads, interrupted here and there by nodular enlargements. In the perfectly formed placenta, both in the human female and the bitch, the vessels which convey the maternal and foetal blood are in intimate apposition. This is effected in the bitch by the first-named vessels being closely enveloped by the villousities of the chorion; but in woman the reverse is the case, the ramifications and the filaments of the villousities being surrounded by the enlarged vessels which carry the maternal blood. If it should eventually be demonstrated that the villousities of the chorion penetrate into the cavities of the uterine glands in the human female as in the bitch, the opinion above given will not be interfered with, for it will still be necessary to prove that the terminal filaments of the villousities are inserted, and, as it were, soldered to the walls of the uterine glands.—*Archives d'Anatomie*, Dec., 1846.

The Cure of Popliteal Aneurysm by Compression.

The improvement introduced by Dr. Harrison's patient, Hoey, of applying a number of clamps along the course of the artery, has afforded a very valuable hint. It would appear it is not necessary completely to arrest the pulsation of the tumour in order to produce a cure; the cure is effected by means of a coagulum formed in the sac, either by lessening the current of blood, or by some peculiar power of coagulation imparted to the blood, aided by the contraction of the sac. Galvanism appears to have favoured this coagulation. From dissections it appears that it is not necessary to obliterate the artery between the point of pressure and the sac, in order to produce the coagulum and effect a cure.—*Editor of Dublin Quarterly.*

Remedy for Facial Neuralgia.—Mr. Sibson, of Nottingham, has enumerated several cases of facial neuralgia treated by ethereal inhalation. The paroxysms of pain appear to have ceased under the influence of the ether. The period of freedom from suffering varies from a few hours to some days. Its employment is likely to be more beneficial in those cases of neuralgia due to a reflected morbid sensation in the facial nerves, excited either in the nerves of the deranged digestive organs, skin, or uterus, than in those cases of neuralgia depending on disease of, or pressure upon, the nerve.—*London Medical Gazette.*

Furor Etheralis.—In Paris, where there is always *une rage* for something to gratify the *gobe-mouches*, it is said to be quite the fashion for the ladies to supply themselves with an apparatus for inhaling ether, and nothing pleases a Parisian lady better than for gentlemen to submit to be experimented upon.—*Parisian Illustrated News.*—[Rather dangerous—we don't know what they might do to us during insensibility.]

Washed ether appears to be less irritating to the respiratory passages, and less nauseating to the patient, than the ordinary rectified ether.

Lithotomy.—It may be stated, as a general proposition, that that mode of performing the lateral operation is the best which effects the division of the prostate gland to the required extent by an incision which shall neither be so superficial as not to admit of the introduction of the forceps without causing laceration of the neck of the bladder, nor so deep as to divide the prostate gland through its entire thickness up to its base.—*Sir. P. Crampton.*—We would add that the lithotomist should stop the cutting movement the moment his *tactus cruditus* tells him that the dense structure of the prostate has been divided.

Lithotomic Division of the Prostate.—I then introduce a fresh sharp scalpel with a blunt back, which is pushed on through the groove obliquely upwards, in a direction towards the umbilicus. The prostate is completely divided on withdrawing the knife, cutting downwards and outwards with a light pressure in the same line as the former incisions, the fingers being still in the wound regulating the action of the knife.—*Brett on Surgical Diseases in India: Lithotomy, p. 206.*

Removal of Loose Cartilages from Joints.—The movable body is secured in the outer and upper part of the synovial bag, if possible, by the pressure of the points of the fingers and thumb of one hand. The knife, which is long, narrow, and slightly curved at the point, is made to penetrate the skin by directing its point perpendicularly to the surface, and at somewhat more than an inch below the substance to be acted on. By a lateral motion of its blade the integument is freely separated from the subjacent parts, so as to make a bed for the lodgement of the cartilage somewhere over the space between the tendon of the biceps and the vastus externus. The point of the instrument is then directed to the foreign body, and made to impinge upon it so as to divide all the interposed tissues and the synovial capsule freely, somewhat in the direction of the limb. The instrument is then withdrawn, and the assistant places the point of a finger on the minute opening. The knife is again introduced towards the outer side, and so managed as to complete a pretty large crucial incision of the immediate coverings of the body to be removed. This done, nothing remains but to pass the point of the instrument under the mass, to disentangle it, to

withdraw it from the joint, and to carry it into the bed previously prepared for it. A bit of plaster is put on each of the openings, and strict rest of the limb enjoined for a few days.—*Liston, in the Dublin Quarterly Journal.*

REVIEWS.

On Tumours of the Uterus and its Appendages. (Jacksonian Prize Dissertation.) By THOMAS SAFFORD LEE, M.R.C.S.E.; Fellow of the Medico-Chirurgical Society; formerly House-Surgeon of University College Hospital, and the Hospital of Women, Red Lion-square; Member of the Royal Medical Society of Edinburgh, &c. &c.

The great objects to be kept in view in medical science are, to acquire an extensive collection of well-authenticated facts; to arrange, classify, combine, or separate; to trace among the facts, sequences or relations, and thence deduce general principles. The author of the volume under review has taken evident pains to conform to these rules.

The first part of the work is devoted to the consideration of benign tumours. Under this head the author treats of fibrous growths. In all tumours of this particular class, affecting the generative organs of the male or female, we are struck with the apparent universality of the fact that they grow to an enormous size. We would illustrate this in the fibrous tumours of the scrotum in the male, and the fibrous growths in the uterus and its appendages in the female. They are essentially benign, and seldom, if ever, degenerate. "Uterine fibrous tumours kill by the obstruction of contiguous organs, not by the extension of disease."

"When situated in the walls of the uterus, these tumours appear to occupy a space between its fibres, and are enclosed in a cyst, to which they are very loosely connected, so that without the slightest force they can be turned out of their bed by the handle of the scalpel. These cysts appear to be thicker in some cases and thinner in others; but they are always present and distinct: and this is an important fact, from the knowledge of which an operation has been proposed to enucleate, or turn out the tumor, by the aid of the scalpel."

"Dr. Hooper and Lisfranc think, that in all uterine tumors the tissue of the uterus is increased—but the former makes an exception: he says, 'This is not the case, however, in all instances: for it is no unusual thing to have large masses of the disease surrounded by very thin and extended uterine fibres.' From the difference of opinion that exists on this point, I have examined many preparations to endeavour to ascertain the truth: I find that the increase of uterine tissue is not always constant. In Guy's Hospital Museum there are several preparations; in some of which the increase of uterine substance is very great, while in others there is a thinning of the fibre over the tumour. In Dr. Reid's case the walls were an inch thick; and in the University College Museum there is an extremely large tumour surrounded by very thin uterine walls. When the tumour projects into the cavity of the uterus, its walls are generally increased in thickness; but when it is situated in its substance, the uterine tissue is most frequently lessened."

The following is quite the character of fibrous growths:—

"It is of a pale ash colour, intersected and interlaced by shining white lines, producing interspaces, which are filled with a dirty white matter: M. Lisfranc believes this to be plastic lymph—Levret compares it to the baked tent of a cow—M. Roux thinks it resembles the intervertebral cartilages of old men."

The treatment recommended by the author is as follows:—Leeches to the tumour itself; the hip-bath, mercury or iodine to the womb, and the mildest cathartics.

"A good form is that of combining a tonic with a cathartic—as the equal parts of the in-

fusion of gentian and senna—two or three times a day, as the case may require; and, if the appetite is failing, a few drops of the nitric acid dil. is a good addition."

Polypoid tumours, cauliflower excrescences, and encephaloid polypi are the next subjects treated of.

The second part of the volume is devoted to Diseases of the Ovary; and the third to Tumours of the Vagina, and the external organs of generation.

The statistical reports which the author has collected from a vast number of sources is anything but flattering to the operation of tapping ovarian tumours.

The tabular statements of the results of extirpation is more favourable; but the character of the tumour is of great importance as regards the prognosis of a successful termination:—

"Of the one hundred and fourteen cases, 65 cases were encysted tumours of the ovary.

16	"	solid tumours.
6	"	uterine tumours.
1	"	omental tumour.
1	"	the cyst of an abscess of ovary.
6	"	no tumour found.
19	"	the particular disease not mentioned.

114
"Of the sixty-five cases of encysted dropsy, 44 recovered. 21 died.

65 or 1 in 3.
"Of the sixteen cases of hard tumour, 9 recovered. 7 died (or nearly half).

16
"Of the six cases of tumours of the uterus, 2 recovered. 4 died.
6."

Coincident organic disease, therefore, must altogether prohibit an operation. The small incision is the least dangerous. "Dr. F. Bird has been successful in six (viz., all) of his operations by the small incision," evacuating the fluid contents, and then removing the tumour. If the incision be sufficiently large to allow of the introduction of the hand of the surgeon into the abdomen, and thus enable him to apply the necessary ligatures, or remove any abdominal attachments to the pelvic viscera, every indication is fulfilled. The mortality by the large incision is 1 to 2½; in the minor operation, 1 in 6.

After-treatment.—The plan which Dr. F. Bird pursues is a very simple but efficacious one:—

"Its object is to place the skin in such a position, as to be able at any period after the operation to cause profuse sweating. This is accomplished by elevating the temperature, and making the patient eat a considerable quantity of ice; this at once produces profuse sweating, and the patient is placed in comparative safety. If, however, pain in the abdomen comes on, the pulse become very quick, and the moisture of the skin be less, he again produces a higher temperature, and continues to do so until the perspirations return. The patient then requires constant watching, and she ought not to be left for many days."

We strongly recommend the work of Mr. Lee as full of valuable information.

Outlines of Structural and Physiological Botany.

By ARTHUR HENKRY, F.R.S., &c., Lecturer on Botany at St. George's and the Middlesex Hospitals, late Botanist to the Geological Survey of the United Kingdom. With eighteen plates. John Van Voorst, 1847. Pp. 245.

At the return of the vernal season, when Nature is again about to put on her gay attire, when the botanist is tempted forth to range the fields in search of wild flowers, and when the medical

Student is about to commence or resume his botanical studies, we have a highly valuable treatise on structural and physiological botany presented to our notice under this modest title. Botany has, at all times, from the days of Dioscorides to those of Linnaeus, Jussieu, Decandolle, Brown, Hooker, and Lindley, claimed the attention of medical men in an especial manner. As we draw a very large proportion of active medicinal agents from the vegetable kingdom, it has been deemed necessary that physicians should be instructed to a certain extent in the natural history of the agents they continually employ. In so far, botany is important to the medical profession. We are not prepared to concede that it is merely in furnishing the sources and properties of vegetable remedies, and the plants that produce them; that botany is of importance to the physician. Since physiology forms the basis on which modern medicine is founded, botany, or rather one department of that extensive science—vegetable physiology—has played an important, although indirect, part in relation to medicine. When we reflect on the intimate connection which subsists among all terrestrial productions,—the web woven by Nature which brings all the objects around us into relation with each other, and renders each subservient to the well-being of the whole; we cannot deny that a general knowledge of the system of Nature is necessary to the full appreciation of any one of the departments into which science has been divided for the convenience of learning and teaching. The physiology of plants bears a close relation to that of animals. The progress of investigation has demonstrated more and more clearly the bonds of connection and mutual dependence of these two classes of living beings. It has shown that the process of generation and development are essentially the same; that all organized beings commence with the cell, and that all the young parts go through phases of development which have their origin in the cell. When so close a relationship is established, the study of the development in one class of beings must throw a vivid light on the same study in the other class; and we may with confidence affirm that a man cannot be a good animal physiologist who does not possess a competent knowledge of the structure and physiology of plants. We would therefore give our most strenuous recommendation, to those who are about to enter on their botanical studies for the first time in the approaching summer session, to devote themselves with ardour to this most interesting department of the study of Nature. Should they in future life be placed in the country, they will derive a considerable source of pleasure from a competent acquaintance with this science. With these preliminary observations, we address ourselves to the examination of the work before us. The limits to which we are confined will oblige us to be brief, and will prevent our indulging in extracts.

The unexampled rapidity with which facts are accumulated, and old facts re-examined, in the present age, furnishes a sufficient apology for the production of the multiplicity of elementary works with which we are at present inundated. Modifications, sometimes of great extent, are thus produced even in the fundamental doctrines of science; and this has been more especially the case in those of animal and vegetable physiology. The proposition, that all animal and vegetable tissues are evolved from cells, is the most striking of the present day. The author has, himself, paid considerable attention to the cell-theory: we can speak of him, from personal knowledge, as a careful and accurate microscopic observer; and we can, therefore, place greater reliance on his opinions on this particular point. The minute structures of which plants are composed are described with clearness and freedom, and accompanied by numerous illustrations, of which we shall speak more particularly hereafter. Having described the minute structures, cells, spiral vessels, woody fibre, &c., he next enters on some general considerations of the physiology

of these elementary structures; and here he follows the Liebigian school. We are not about to enter on a general review of these doctrines, although we think it necessary to caution our young friends against an implicit reliance on the long rows of symbols and equations which are so profusely distributed through the celebrated work of Baron Liebig. The acetous fermentation is brought forward as an example of the chemical changes occurring in nutrition. The changes of alcohol into acetic acid during the acetous fermentation is intimately connected with the production and growth of a fungus, to which the name *mycoderma vini* is applied, but which is really formed of the undeveloped plants of one or other of the com-moulds (*mycetes*). The production of these moulds is thus explained:—

	C.	H.	N.	O.
74 of water (H. O.)	94	74	..	74
94 of carbonic acid (C. O. ₂) ..	94	188
2 of carbonate of ammonia N.H. ₃ C.O. ₂)	2	2	6	4
	96	76	6	266
From which are formed—				
1 proteine	48	36	6	14
4 cellulose	48	40	..	40
212 oxygen	212
	96	76	6	266

And, as four equivalents of oxygen must combine with one of alcohol to form acetic acid, fifty-three equivalents of alcohol are changed into vinegar. These figures look very pretty on paper, and afford at first sight a very plausible explanation; but they give a totally and entirely false representation of the phenomenon of acetous fermentation. The elements here employed are not those which enter into the acetous fermentation. If water, carbonic acid, and carbonate of ammonia, are the active principles of the acetous fermentation, the fermentation should proceed with as great freedom in an atmosphere of carbonic acid as in contact with common air. Our wine and beer would be quite as liable to be converted into vinegar while in the cask as when freely exposed to the atmosphere, and would, for that reason, be incapable of preservation. The air contained in the upper part of a cask is strongly impregnated with carbonic acid; the putrefaction of the nitrogenized matter contained in beer and wine, and their conversion into carbonate of ammonia, may go on without any considerable supply of oxygen, and thus all the conditions for the acetous fermentation would be supplied. Facts are opposed to this view; for acetous fermentation does not usually take place, and, when it does, it is small in extent, and may be in most cases referred to exposure to air. According to the explanation given above, a larger quantity of oxygen is set free. Now, we well know that, during the whole progress of the acetous fermentation, oxygen is absorbed from the atmosphere. Alcohol having the composition C₄H₁₀O₂, if we take from it three of hydrogen and add one of oxygen, acetic acid, C₄H₈O₂, will be formed. Thus each equivalent of alcohol requires four of oxygen to convert it into acetic acid, which is absorbed from the air; three of this equivalent combining with three of hydrogen to form water, the remaining equivalent being employed to oxidize the aldehydic acid, and convert it into acetic acid. Other explanations may be given of this series of chemical changes, equally correct as regards the atomic numbers involved in the conversion of alcohol into acetic acid. We conceive that we have sufficiently demonstrated that the explanation given in the work before us is incorrect. With regard to the production of proteine, we have no evidence that carbonate of ammonia is ever produced; for the pressure of a large quantity of alcohol and acetic acid in the fluid would suffice to prevent the putrefactive fermentation from proceeding to its full extent. Our author, with becoming caution, subsequently warns us from placing too great a reliance on these explanations.

The plant, as an individual, and the modifications of the parts of which it is composed, occupy the fourth chapter; the axis and its appendages the fifth; ramification, the sixth; the physiology of vegetation, absorption, circulation, respiration, assimilation, and secretion, the seventh; the eighth and ninth are devoted to reproduction, while the tenth contains some miscellaneous general observations.

Such are the contents of a volume, which does great credit to the science and industry of its author, and brings our knowledge of botanical science down to the present period. After a careful perusal, we can confidently affirm that it may be placed on the same shelf with the well-known elementary works of Lindley; in saying which we accord no small praise to the work. We have only one fault to find, and that is with the plates, which are not so distinct as they might have been made. Zincographed and lithographed plates are always less distinct in outline than engravings on copper, steel, or wood. They are, however, much less expensive, and we presume that the object of the author was to afford abundant illustration in the most economical form. The eighteen plates contain several hundred illustrations of structure, and we can safely say that Mr. Henfrey has succeeded in furnishing the student with one of the cheapest and best manuals of structural and physiological botany.

An Inquiry into the Sanitary State of the Town of Lynn Regis. By GEORGE SAYLE, M.R.C.S., &c. &c. 8vo., pp. 22.

This pamphlet is rather of local than of general interest, but it nevertheless claims our notice, on account of the active spirit of hygienic good intention contained in it. Mr. Sayle, as an intelligent, judicious practitioner, cannot see the opportunities of fever and pestilence lying in his every-day course, without communicating the appalling fact to the authorities, and bidding them see that such human nuisances are forthwith cleared away. Whether the stolid local functionaries have sense enough to profit by Mr. Sayle's suggestions, time must prove; that they need do, is pretty evident from the following passage, concerning a certain locality of the town in question:—

"Immediately joining the boundary wall is a stagnant gutter, the carrier of refuse matter from the infirmary to another large drain, which *ought* to empty itself into the adjoining fleet. Contiguous to this wall are three or four piggeries.

"On the east side of the road to the rope-walk, are from fifteen to twenty more piggeries, slaughter-houses, and carrion-dens, with a pit in their centre, full of refuse matter, far advanced to a decomposed state." (P. 18.)

Such facts are powerful enough to plead for themselves; but there are some people whom the naked truth will not reach. Mr. Sayle backs his truths by reasoning, which no rational mind can be proof against.

Letters to the Right Hon. Lord John Russell, M.P., on the Subject of the Drainage of the Metropolis; State of the Thames; and the Waste of Fertilising Substances. 8vo., pp. 15. London, 1846.

The author of this able and well-timed pamphlet deserves the best thanks of the public at large, and of the London public in particular, for the judicious views he has taken of the several important subjects embraced in its title. These he has investigated, in their various relations, with much deliberateness, and with the nice calculation of a man at home in such business. He has not only adventured in the spirit of trying and testing it thoroughly, but he has produced many items and calculations, and *proofs* of a better system of drainage and sewerage of the metropolis than at present exists. These are questions of the highest import in large towns, where congregated, crowded people cannot but feel, most disastrously, the effects of bad street and sewer management. Communications of the

nature of the one lying before us must be regarded by philanthropists in the light of substantial services: this is our view of the pamphlet in question; and, though our space does not permit us the opportunity of quotation, we gladly commend it to the notice of the very many who must be interested in it.

TO CORRESPONDENTS.

THE MEDICAL TIMES may be procured by an order on any Newsmen or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Corfray, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 13s.; Quarterly, 6s. 6d.

A HANDSOME PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 5s. An allowance is made to the trade.

X. Y.—An appointed vaccinator cannot receive the union payment in addition to private remuneration for the same labour.

Mr. T. B. Smith writes us a long letter, insisting that there should be two examinations of the student—one somewhat elementary, the other in the highest range of medicine and surgery.

Machaon, who treats Brodie's lectures as some people, according to Falstaff, would treat kittens, is informed that they were delivered this session, and were announced, by advertisement of the Hospital School, as "important." From the disparaging way in which our correspondent speaks of Brodie, Guthrie, Tyrrell, Abernethy, Cooper, &c., we suppose him to be some unknown prodigy of surgical skill; or, what is perhaps equally possible, surgical impudence. The disparaging diathesis, so common in some parts of the profession, is not, we fear, a demonstrative proof of genius. As for the course of lectures we have announced, we shall publish them all in rapid succession. It is impossible, as our correspondent must feel on reflection, to give them all simultaneously.

We have no space for the communication of Truthseeker, which is sent to us anonymously.

Mr. Owen Richards's suggestions will be borne in mind.

Dr. John Thompson's reply to our article of last week is inadmissible. It would be neither instructive nor useful, nor scarcely amusing, to publish demonstrations that every man is a quack, although we might be so assured by a subscriber who is a medical man himself.

A Medical Student's defence of the Edinburgh Infirmary forgets its object in wordy abuse of Dr. Thompson. Either no defence was necessary, or our correspondent has wholly failed in his design.

We quite agree with our correspondent that the abuse of the Coroner's Court requires speedy correction. We are maturing a plan which will, we hope, effectually protect the profession from injustice in every part of the country.

It is impossible that we can publish many of the communications with which we are honoured. Our correspondents must content themselves with the assurance that our discretion is carefully exercised in the selection.

W. Y.—We propose concluding each series of lectures as rapidly as possible, and commencing fresh courses as the ground is cleared for their going on without intermission.

We regret to say that the extensive claims on our space preclude our entering, with Dr. Collyer, into the contest about his prior claims to the discovery of ether inhalations. There is nothing less interesting to us than intervention between gentlemen and the injustice of our contemporaries.

We have no leisure to examine the value of Mr. Woolcott's suggestion.

Medicus is thanked for directing our attention to the cases of gross neglect he names. There can be no doubt that the guilty party can be indicted under the Apothecaries' Act.

M. D.'s case should have been authenticated.

Mr. Henderson's note has been received.

The Third Part of Mr. Rilles's Views on Sudden Death will be in our next.

A Military Surgeon.—We have in no way interposed about the subscription—nor shall we. Our expenses in the Hounslow inquest affair have been much exaggerated. They were under two hundred pounds.

In answer to numerous inquiries about Sir B. Brodie's lectures, published by us in the last and present volumes of the Medical Times, we have again to notify that they are the lectures delivered at St. George's Hospital, during the present session, by the learned baronet. The course being short, and addressed more particularly to students, we have published them in the most modest form, and without any attempt to invest them with an extrinsic importance. They have been announced, we perceive, in other quarters more ostentatiously, and, as usual, not given.

Blue Jacket!—Order "Williams's Lectures on Plethora," through a bookseller. We have no time to find out the numbers of the Medical Times containing the lectures on the subject. 2. We do not give "advice gratis." 3. The camphorated dentifrice is as good as any other.

Our readers and the public are reminded that the fourth lecture (containing twenty-six beautiful engravings) of Muller's superb work on *Physic* appears in the Pharmaceutical Times of to-day. Vol. 1 of the Pharmaceutical Times is now ready, in half cloth, 10s.; half-bound, 11s.

An Old Army Officer's letter should be sent to one of the Army and Navy Clubs or journals. We will have nothing to do with promoting any such subscription.

A General Practitioner, who has secured us, by personal canvass, three new subscribers to the new volume, is desired to receive our best thanks. Such efforts are, indeed, encouraging.

We are unable to answer Mr. Copley's questions.

Mr. Crooke cannot do better than take his degree where he is.

E. D. D.—We must decline to name any one book as the best. The duty is too invidious.

Mr. Poffle.—We have received the beautifully-illustrated copy of the New Testament, published at the office of our Illustrated contemporary; but it is not our custom to publish lists of the books sent to us.

We have some communications in type, which will appear in our next number.

We have also to acknowledge communications and letters from Mr. Shave, Coldfield; Mr. Hutchinson, Bridlington; Mr. Lucy, Poole; Mr. Butler, Guildford; Mr. Beedell, Ticeyton; Dr. Lee, Northwich; Mr. Medd, Stockport; Mr. Green, Wellington; Dr. Hamilton, Leamington; Mr. Barton, Ulverston; Mr. Macley, Glasgow; Mr. Counsellor, Gateshead; Mr. Nolan, Wicklow; Mr. Butcher, Ware; Mr. Campbell, Liverpool; Mr. Morris, Banbury; Mr. Hamming, Halton-on-the-Hill; Mr. Ricketts, Droitwich; Mr. Nicholson, Stilton; Mr. Patts, Cranbourne; Dr. Healy, Dublin; Mr. Johnson, Wallington; Mr. Sutton, Langdon; Mr. Pade, Plympton; Mr. Joy, Northwood; Mr. Ritchie, Tean; Mr. Walford, Blackheath; Mr. Morgan, Newtown; Mr. Kingston, Harpenden; Mr. Newland, Dublin; Mr. Magee, Rotherfields; Mr. Cornack, Putney; Mr. Brady, Watford; Mr. Beale, Driffild; Dr. Murray, Monaghan; Dr. Lers, Ashton-under-Lyne; Mr. Leake, Pontefract; Mr. Patten, Kyring-lane; Mr. Jordan, Manchester; Mr. Pye, Runcorne; Mr. Essex, Pontypool; Mr. Clifton, Welwyn; Mr. Pennington, Liverpool; Mr. Newman, York; Dr. Probert, Bury; Mr. Hine, Coventry; Mr. North, Brecon; Mr. Coates, Salisbury; Mr. Fletcher, Bury; Mr. Harrison, Deptford; Dr. Steadman, Wellington; Mr. Stephens, North Shields; Mr. Wilkins, Mullingar; Mr. Turner, Deddington; Mr. McIntire, Coleraine; Mr. Croome, Banbury; Mr. Clarke, Aldboro'; Mr. Phillips, Sagen Palden-hill; Mr. Williams, South Brent; Mr. Gill, Liverpool; Dr. Finlay, Rackcorry; Mr. Watling, Leominster; Mr. Harmer, Wrentham; Dr. Brown, Dunfermline; Mr. Robinson, Newbury; Mr. Pile, Taunton; Dr. Sykes, Cleckheaton; Mr. —, New Shore-

ham; Dr. Gartick, Halifax; Mr. Broton, Castle Downington; Dr. Davis, Outerlands, Didsy; Dr. Robertson, Manchester; Dr. Taylor, Bradford; Mr. Turner, Manchester; Mr. Harrison, Braintree; Dr. Little, Sligo; Mr. Meredith, Tisbury; Mr. Stamp, Seaton; Dr. Christie, Sealaw; Dr. Taylor, Askeaton; Mr. Stevens, St. Keweenaw; Mr. Guyan, Freshford; Mr. Christie, Ashdown; Mr. Mullin, New Ross; Mr. Spencer, Shilton; Dr. Sandiford, Carrigaline; Dr. Keagh, Dublin; Mr. Maclean, Elgin; Mr. Bonnas, Mr. Brad-don, Upton-on-Severn; Mr. Heale, Luton; Mr. Kent, Upton-on-Severn; Mr. Dawes, Albany Barracks; Mr. Jones, Milford; Mr. Payne, Aber-gavenny; Mr. Corfield, Camden-town; Dr. Gelston, Limerick; Mr. Price, Cardiff; Mr. Adamthwaite, Stanhope; Mr. Chaynell, Maddox-secret.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the SCIENCE of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is then for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract love of a pedantic and inapplicable lore. Every power of his mind is engaged; he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate, to be EXPERIENCED: each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diplomas or licenses.

Six of the cases are to be medical, and six surgical. The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the Medical Times, with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is bona fide a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, MARCH 20, 1847.

THE JUDGMENT.

We direct our readers' attention to a meeting reported in another page. The West Middlesex Coroner has been twenty years or more in active political life; and, when we take into account with that circumstance his high respectability of character and remarkable eminence of intellect, we ought, perhaps, not to be surprised that the wide public advertisement and placarding of his name in connection with an anti-flogging meeting should secure him a metropolitan attendance of as many as—thirty hearers! In the Angel Inn, Finsbury, a donation of tickets, even in these days of dietie

popularity, will attract to him as many as sixty sterner companions; and, in the pugilistic establishment of Drury-lane, the attractions of the house, if aided by a clever and energetic system of advertising, and a popular grievance, will actually bring about him an auditory of three ten! Undoubtedly, the honourable gentleman is entitled to our compliments on the magic extent of his political influence! Well might he say that he looked on such an attendance with pleasure and no grief. Truly he has not laboured in vain. How we envy him the reflections which such a result of a whole life's ceaseless activity must inspire! Yet, with all our admiration at the success of the Coroner's career, we must be pardoned an expression of regret that he again compels us to make our belief in his judicial equity and fair dealing dependent on the disbelief of those qualities in the Court of Queen's Bench. This is a severe trial to our feelings of partisanship and admiration of the honourable member. It, of course, costs us nothing to believe him a paragon of magisterial perfections; but, if that belief be inconsistent with giving Lord Denman and the other Judges of the Court of Queen's Bench credit for something like a love of justice and a knowledge of law, we must fain put up with a few doubts slightly—very slightly—to the disadvantage of the inferior functionary.

As might have been expected from the known benignity and kindness of heart of the West Middlesex Coroner, the rejection of Dr. Warren's testimony was all for Dr. Warren's good. Dr. Warren, if by any chance the evidence could trace death to the flogging, might have been tried for murder; and, therefore, Dr. Warren's evidence—voluntarily tendered—which would have proved that the death was not caused by flogging, was not taken on oath. True, it was kindly taken verbally and unsworn; and in this way Dr. Warren received two advantages: his statements would have no weight with the jury, and would tell against him on any future possible proceedings quite as much as if they had been sworn. Dr. Warren ought to be grateful for a kindness all the more real as it was difficult to make it discernible to him.

Considering that a brother medical man's life was in peril for a merely perfunctory duty, we don't wonder that the benignant magistrate sanctioned a few inquest irregularities, and we are prepared beforehand to find them leaning to the side of his exculpation. Hence was it that the statute was put aside, that Dr. Warren might not be heard: hence was it that as the Queen's Bench declare, injustice was done in not taking down his testimony on oath: hence was it that Mr. Day was now illegally appointed, and now illegally refused a hearing: hence was it that Drs. Reid and Hall had their evidence kept back from delivery and publication for fourteen days or more: hence was it that they were excluded from the inquest room on one occasion and the post-mortem examination on another: hence was it that they were treated, as three witnesses swear, with rudeness, discourtesy, par-

tiality, and worse: hence was it that Mr. Wilson, a private associate and friend, was brought in, in direct contravention of the statute: hence was it that his evidence took on so favourable a character to Dr. Warren: hence was it that Dr. M'Kinlay, who was known to have attended one of the post-mortem examinations, was never called: and hence, finally, all the other irregularities which have given the inquest so extraordinary a notoriety, and won for its honourable president and his journal so deep a gratitude, expressed in every possible form, on the part of all medical men!

Agreeing on so many points with this worthy magistrate, we may be charged with a hypercritical fastidiousness when we declare that we do not quite like the attempt, in his speech, to cast disrepute on Lord Denman as a "denier of justice," or the promise "to correct," as "an inferior coroner," "the mistakes of that chief coroner;" or his assertion that Drs. Reid and Hall, in obeying special orders, in accordance with military regulations, and making an autopsy of a deceased soldier, "acted against their duty;" or the argument, that because a small bruise or burn may be speedily followed by death, every man flogged must be killed; or the principle that coroners should reward pecuniarily their own witnesses; or, in short, any other part of the speech delivered to the visitors of "The Craven Head" public-house, Drury-lane, London.

"Fortes erant illi fortibus."—HORACE.

ON the authority of the Provincial Medical Association, and its organ, we last week gave our readers some important facts. The Association had seen Sir George Grey. This was undoubtedly something. Some people can go geese to Hatter and come back geese; and the ill-natured may surmise that the Provincial Committee might have hob-nobbed for a quarter of an hour with all the metropolitan intellectuality of Grey, and returned a very Provincial Committee still. There could be no greater mistake. The council, by their visit to London and their interview with Sir George, were enabled to go away laden with—we use the magnificence of their own description—"hopes"! "From the result of this interview," say they, "strong hopes are entertained that a settlement of the questions connected with Medical Reform, satisfactory to all branches of the profession, may be obtained." Sir George Grey is so magnificent in his promises that the provincial deputation return with "hopes;" not of a settlement indeed, but of—what is almost as much—its possibility; and the worthy deputies are so proudly elate at the important news that they lose no time to communicate it by sound of trumpet to the whole profession. They have actually seen the great Minister, and a "settlement may be obtained"; no—not quite that—there are "strong hopes that it may"! We can appreciate the emotions of the less favoured members when this pregnant assurance of good news is conveyed to them; and we would that the official newsmen was not obliged by truth to damp the ardour of their exuberant gratitude, or impair the excesses of their unspeakable delight, by such disheartening reservations or conditions as the following:—"These hopes are, however, dependent upon

some approach to unanimity in the concession of minor points being manifested by the different sections of the profession." Is it not heartbreaking, and enough to put a saint out of temper, that these magnificent "hopes" of a delightful possibility—a most enchanting "may-be"—shall be made dependent on the "manifestation of an approach"—an approach utterly unapproachable—a possibility, in fact, dependent on an impossibility?

The cup of Tantalus was bliss itself to the "strong hopes" that the Provincial Council now handsomely commend to our lips, now so cruelly dash to the earth. After a laborious and costly mission to the metropolis—at a time, too, when the season was hardly commenced, the Italian Opera but just opened—and after an actual interview with a real, live Minister—to find ourselves blessed with a hoped "may-be," which, we are told, may not be! Is it not intolerable?

Alas! we wanted no ghost, still less a Provincial Council's interview with the Home Secretary, to inform us that Medical Reform might be settled if the different sections of the profession would "concede" and become "unanimous." The world has long known that there is a capital dish in that said "unanimity"; but the work has been on Mrs. Glasses' prudent principle—how first to catch it? *Hoc opus hic labor est.* Still let us not be ungrateful. A thankful heart will be hard put it for the relief of its emotions, if it will not disburden itself on small mercies. The Provincial Council has existed about the sixth of a century; it has consumed, probably, from £20,000 to £30,000 of professional taxes; and that it has not spent its life or cash wholly in vain is demonstrated by the fact that, in 1847, they can announce on the highest authority—their own—that we may have "hopes" that there "may be a settlement," provided, in the first place, that all sections of the profession will only be "unanimous" on it! With such an achievement in the cause of Medical Reform before us, we might well be called slanderers if we could breathe a syllable against the way in which the Provincial Council has discharged its onerous trust to its many confiding and worthy constituents. "Scurrility," "personality," "libel," would be the least striking of the imputations our hardy injustice would merit!

A sad thing, be it said in conclusion, is that same word "unanimity." It sounds on our ear as the enchanted land vision looks to the eye of the sea-worn mariner. It is a "strong"—a very "strong," but at the same time a very illusory, "hope." There is nothing of it in any part of the professional system. It is not in us nor of us. Complete ignorance or consummate knowledge—either may beget uniformity: it cannot come of a profession like ours, in which all degrees of talent are met in unison with all variations of information; and wherein every man is his own lawgiver and guide, alike incredulous and self-confiding. Our unanimity is in dissent—our combination is each man to be his own leader. As in nature our functions are for reparation; in politics they are for destruction. United to recognise a social disease—we are never so to cure it. How vain, then, the "hope" of "unanimity":—above all, how vain the "hope" of "unanimity" in conceding!

ROYAL COLLEGE OF SURGEONS.—Gentlemen admitted members on Friday, March 12th.—G. Allbut, C. M. Empson, H. Barnett, H. Green, W. Faithfull, J. M. Birom, J. Rice, and C. P. Hugo.

ETHER OPERATIONS.

The kind interest you have taken, and continue to manifest, in the apparatus ("Martin's Pneumatic Inhaler") I have contrived for introducing into the lungs any medicinal substance, which can be converted into gas or vapour, and thus mingled with a proper proportion of air or steam, or both, to render it respirable, induces me to request your insertion of a few remarks on the subject of ethereal inhalations.

The approving notices with which the instrument referred to has been honoured in the pages of your journal, by directing the attention of nine-tenths of the profession to it, has afforded me unusual opportunities, not only of testing its efficacy under all the circumstances for which it was designed, but also becoming practically acquainted with the effects of ethereal vapours in the human economy, whether these may have been administered to produce insensibility to pain in surgical cases, or as remedial medical agents. In addition to which sources of experience, I have personally breathed etherized air until the advent of unconsciousness, not less than twelve or fifteen times, and have administered the same to numerous members of my own family and others, both in a state of health and indisposition, more than a hundred times; besides, scarcely a day passes that is not marked by some novel point of suggestion from the numerous correspondents your advocacy has originated; or, which account, indeed, I now appeal to your well-known liberality for the insertion of the little I know on this subject, as you will thus supply my answers to the different queries that have been addressed to me; at the same time giving rise to extended research on the subject. I may also mention, as a second inducement for the intrusion of my remarks upon you at this moment, the fact of a few sinister accidents, and even deaths, from the effects of ether in vapour, having come to my knowledge; not, however, I am truly happy to say, under the use of the pneumatic inhaler, which, as yet, has encountered no such unfavourable results, nor, indeed, is it likely to do so, as I believe it possesses the power, when judiciously employed, of materially lessening, if not of entirely obviating, such unhappy occurrences.

The inhalation of ether for producing "insensibility to the pain of surgical operations" is a new discovery that will confer immortality on the name of Dr. Morton, of Boston, United States, although it may be hereafter determined that some one else shall share with him the merit of having suggested a remedy he has so successfully applied and carried out. Yet ethereal vapour as a remedial agent has been known and employed nearly as long since as the date of the introduction of ether as an article of *matéria medica*. Ether in vapour has even been publicly breathed after the manner of nitrous oxide gas, to produce analogous effects to this agent, in certain chemical lecture-rooms in London, for some years past. (a) Yet it must be recollected that the pure vapour of ether is not respirable for many seconds, so that in all these experiments there must have been a greater or less admixture of air: a circumstance never to be forgotten in the construction of any instrument employed for inhalation of this vapour, as to such omission alone the deaths, accidents alluded to, are to be ascribed in every instance which has hitherto come under my notice.

To facilitate the consideration of the subject, I will arrange it under the three following divisions:—

1. As to the qualities of the ether itself.
2. As to its effects on the healthy or sick, in its simple or combined forms.

3. As to the qualities necessary to constitute a complete, serviceable, and innocuous apparatus.

With regard to the first division, the sulphuric ether used for inhalations should be perfectly pure, free from acid or alcohol, of the specific

gravity of 730; and a quantity, not exceeding half a drachm, of ether of this purity, should be converted into vapour and mingled with three pints of air for each single separate inspiration. And the supply of ether and air should be so regulated as to furnish this proportion at each successive inhalation, taking care that the whole quantity consumed do not exceed two ounces at the most.

Admixtures of sulphovinic acid, (etheral oil as it was formerly called) with the ether, or of free sulphuric or sulphurous acid, or of alcohol, have the effect of modifying the action of the remedy, either by causing irritation in the air passages, and thereby producing cough; or, in the case of alcohol, of substituting intoxicating for narcotic qualities.

I have found no ether of equal efficacy with the sulphuric, nor can any be breathed which produces so slight a degree of pulmonary irritation. The effects of the vapour of ether on the system, forming the second division of the subject, I need scarcely add, will materially differ according to the application and the purity of the spirit.

With regard to the effects of inhaling ethereal vapour properly mixed with air: they vary according to the state of the patient, the disposition his mind may be in prior to his commencing the operation, and the mode in which the vapour has been administered; but in a large majority of cases, with the ordinary class of instruments and in my early experiments, I found a few inspirations have been followed by much irritation of the bronchial membrane, inducing feelings of constriction in the throat, with sensations of suffocation almost as great as though carbonic acid were inhaled. It is thus after numerous trials I discovered that one part ethereal vapour and two parts air constitute the highest admixture which can generally be inhaled, without defeating much of the effect of the remedy by irritating the lungs. If a proportion of steam be added to the extent 1-10 to 1-6, the remedy is rendered so much milder that it scarcely disturbs the natural freedom of inspiration, even in irritable cases; a further addition of steam would appear to render the action of the ether comparatively impotent as an agent for producing insensibility to pain, but very efficacious against many affections of the respiratory organs, as catarrh, certain stages of bronchial affection, and spasmodic asthma—the paroxysm of which it seldom fails to suspend.

It has been stated, with much truth, that the effects of ethereal inhalation are marked by three principal stages, which gradually lapse or blend into each other. The first has been regarded as the stage of excitation, evidenced by ardour or flushing of the face, slight increase of pulse, and actions, looks, gestures, or speech, which betray excitement. The second stage is marked by unconsciousness and sensibility, depressed pulse, long inspirations, and general relaxation of the muscular system, commonly so complete as to prevent speech and motion. The third stage is manifested by faintness or complete syncope, attended with stupor and unconsciousness, small or imperceptible pulse, collapse of all the vital functions, coldness of the surface, palor of the face and lips, clammy perspiration, loss of muscular power and action, even in the muscles of respiration, and finally by death itself.

It can scarcely be necessary to observe that this stage of collapse results either from the administration of the ethereal vapour in too concentrated a form, or in too large a quantity, or too great a length of time, or, lastly, from peculiar idiosyncrasy in the patient; and that happily it is very rarely witnessed, if common prudence be observed, and an apparatus employed in which the exact quantity of ether used and proportions of it inhaled can be measured both by the hand and eye: therefore, on the latter account, the apparatus should be of glass.

With regard to the third part of my subject, "the necessary qualities of the apparatus to be employed," it will be perceived, from what has been

said regarding the purity of the ether, that if such apparatus could contain within itself the means of correcting any accidental impurity, it would constitute a great advantage; for instance, if warm water, or an alkaline liquid, were in the receiver, not only would the evaporation of the ether be ensured, but any alcohol or free acid would be dissipated, whilst, if the temperature of such liquid were above 100° Fahr., the conversion of the ether into vapour would be secured; and, as it would seem advisable to be enabled to regulate accurately the quantity of ether in vapour taken into the lungs at a single inspiration, the means of accomplishing such an end must be a *sine qua non* in the perfection of the apparatus. The next point requiring our attention is the fact that a single inspiration requires from three to four pints of æriiform fluid for its accomplishment; consequently the apparatus must hold so much, which must be in a manner confined to ensure its admixture with the ether when vapourized, whilst there shall be a free communication between it and the lungs, so that the trachea shall have a supply of etherized air fully equal to its calibre. Finally, some substitute a second pair of lips; and a second glottis will be required to enable the vapour to be inspired and expired, without being returned again into that part of the apparatus wherein it was generated; and all this should be so managed as to interfere as little as possible with the natural freedom of respiration.

Such are the requisites for a perfect apparatus, which would be further improved by being rendered portable, inexpensive, and readily repaired in case of accident. I can assure you I have laboured in this field, and I believe, in common with all inventors, have had to deplore many omissions and commissions over which I have had no control. In the firm of Messrs. Maw and Son, I hope to have discovered the object of my search, so that my professional brethren may be supplied with an instrument which shall satisfy them both in its workmanship and cost, and which shall contain all the requirements before mentioned, in addition to being applicable to all kinds of inhalations, of which, with your permission, I purpose rendering an account on some future occasion.

I am, dear Sir, your obedient servant,

JAMES MARTIN.

3, Finsbury-place South, March 17,
17th March, 1847.

EXTENSIVE FRACTURE OF THE SKULL, AND RECOVERY THEREFROM.

By J. R. TORDOCK, M.D., Kirkcaldy, Scotland.

Thomas Thistlethwaite, a youth about thirteen years of age, whilst engaged attending a mason, in the employ of Messrs. Burdges, of Carley-hill Lame-works, near Sunderland, had the misfortune to have a stone of considerable magnitude, fall upon his head whilst in the kiln bottom. He was taken up in a state of insensibility, and conveyed home. On my arrival, accompanied with my friend, Mr. H. Taylor, surgeon, we found him stretched upon a table and apparently in *articulo mortis*; no pulse, either at the wrist or temples—indeed there were no visible signs of life. The symptoms were those of compression of the brain, the pupils were much dilated and immovable, and there existed a total loss of all consciousness. Notwithstanding, we proceeded in our examination, when we found an extensive lacerated and contused wound of the scalp, extending from the front to the back of the head, in a line corresponding with the frontal sinus. On removal of the scalp, so as to ascertain the nature and extent of the injury, we found a fracture extending in a direct line from the frontal through a portion of the occipital bones, above six inches in length, attended with considerable depression. On applying the elevator, it was evident that injury had been done to the longitudinal sinus, not less than from five to six ounces of dark venous blood escaping; we also found the dura mater

(a) Under the eye and by the direction of Dr. A. T. Thompson and others.

lacerated and covered with bloody serum. At this stage of our proceedings I was requested to desist as "the boy was dead." Nothing daunted, we persevered, elevating the fractured portions, and removing others; the brain was now freed from pressure, and after a short interval, to the astonishment of all present, the sufferer heaved a faint sigh; the region of the heart was now subjected to friction, with warm stimulants, and every means followed out to procure reaction. This was at last accomplished, after considerable perseverance; suitable diet was enjoined, with quietness, attention to the bladder and bowels, and, as symptoms of an untoward character manifested themselves, depletion by the lancet, leeches, &c., but with great caution. He continued in a state of insensibility for several days, voiding his motions involuntarily; the pulse was never quick, but, on the contrary, slow and very irregular, and any one not conversant with the case from its commencement would have been led to conclude that each successive beat of the pulse was the last and closing operation of the heart's action, such was its peculiarity: he was not able to speak for some time, and, when he became conscious, complained of great pain in his head, not bearing the least noise, the inquiries having to be made in a whisper. Every symptom was narrowly watched; mercurial preparations were given to induce gentle pyrexia; blisters to the back of the neck and extremities; due attention to the bowels—viz., mild aperients, enemata, &c., the nourishment being varied according to circumstances. He continued thus to linger for two months, when he gradually recovered; the scalp was healed, and there remained a longitudinal furrow, in which the thickness of a finger might be imbedded. Notwithstanding, he is now entirely recovered, and enjoying robust health, and has been for some time engaged in the business of a ship-carpenter, which is a very laborious calling. Three years have now elapsed, during which interval he has never complained in the least of pain in the head, and the normal functions of the brain have never been interrupted.

THE MATTHEWSON AND COOKE SUBSCRIPTION.

Pursuant to public announcement, a meeting was held on Wednesday, the 10th instant, at the Craven's Head, the well-known sporting house in Drury-lane, for the purpose of completing a subscription, begun at the meeting at Exeter-hall last August, for procuring the discharge from the army of two privates of the 7th Hussars, whose evidence was found so useful at the memorable Hounslow inquest. At seven o'clock, the hour named for the chair to be taken, the room might perhaps have held ten persons, the number steadily increasing till at eight o'clock it reached the maximum of thirty individuals. The audience, who till this time had in silence supported an exemplary equanimity, began to leave the room, and the treasurer and secretary appeared not a little uneasy at the absurdity of the position into which they had brought the persons present, including themselves; ominous shrugs and significant whispers were rife: "can't get the steam up," "must tell them something," "better adjourn," "awkward fix," were the expressions interchanged between the two gentlemen. At last, some time after eight, the chair was taken by the treasurer, who called on the secretary to read his report. This document, after alluding to the commencement of the subscription in Exeter-hall, and the enthusiastic exertions which had extended from London over the country, stated that this feeling had been of brief duration, and, although the sum proposed to be raised did not exceed £50, £35 only had been gained—a sum which included certain doubtful sums, the receipt of which might be speculated upon.

This decadence of the public sentiment gave occasion to some very appropriate remarks on the fickleness of the national character, followed

by an imploring appeal to the generosity of the meeting. The secretary stated that, in order to give the greatest publicity to the announcement of the meeting, the most approved methods of advertising had been put in requisition; the result was thus rendered still more unaccountable. After some ineffectual endeavours to create a sensation in the assembled few, Mr. Wakley put an end to the difficulty, as will be seen in the subjoined report of his speech, by undertaking himself the completion of the subscription.

Mr. Wakley said—Mr. Chairman, I do not see any reason for so much grief as has been expressed at the small attendance of this evening, or the scarcity of the subscription; on the contrary, I think that the manner in which the contributions have been raised, by penny subscriptions, gives us evidence that, in the prosecution of the great object which we all have at heart, we carry with us the sympathies of the public. It would indeed be discreditable to the public if, knowing the circumstances in which Mathewson and Cooke stand, they had not contributed their mites. It is monstrous that a man who comes forward and gives his honest testimony upon oath—that such a man should be compelled to feel that in doing so he may place himself in a situation of difficulty and danger; and it is of the greatest importance that over such a man the shield of public protection should be thrown. Now, in this case, the private Mathewson appeared to me to give honest testimony, and I must say the same also of Cooke, without anything of an exaggerative character; and every statement was supported by other evidence. Is it not monstrous that men who had only honestly discharged their duty should be allowed by their fellow-citizens to be exposed to suffering on that account? I say, it is in the highest degree discreditable that these men should be allowed to remain in the position of danger in which their honest testimony has placed them: they have by their manly conduct incurred the ill-will and displeasure of their superior officers. A short time after the evidence of Cooke had been given, he was singled out from the rest, and the whole battalion was ordered to fall back and leave him alone to stand forth as a man who had done wrong, though his only offence was that he had spoken the truth on oath. Cooke is a member of a most respectable family, and was held in esteem, as was shown by the privilege which was awarded to him of having a room exempt from the presence of a corporal; but shortly after his evidence had been fearlessly given his room was taken away and a corporal placed over him. I believe the Hounslow inquest has achieved a great public good; as to myself, I have only done my duty. I set out on the inquiry with that determination from which nothing could induce me to flinch. I held the inquest under suspicious, shared in by gentlemen and magistrates, that the unfortunate man White had died in consequence of the flogging, and I conducted the inquiry with reference to that suspicion; it was a duty which I owed to the crown and to the public. The clergyman of the district, himself a magistrate, was told that the man had died of diseased liver; and from the multiplicity of the reports in circulation there was the greatest difficulty in getting at the truth; and, having commenced the inquest, I determined to take no evidence till the body had been well examined, both externally and internally. It has been a troublesome and painful thing to me; but a man never feels pain when he knows he is doing his duty; and the results give me the greatest satisfaction. No feeling that I had with reference to the practice of flogging influenced me; but I merely did what I thought, by the oath of my office, I was bound to do. The conduct I pursued has led Lord Denman to deny me justice. A calumnious public writer had charged me with having participated in the fees of the inquest with one of the medical witnesses, and I moved for a criminal information. Shortly after the publication of this calumnious statement, I was attacked in the House of Commons, and I

defended myself. But what does the Court of Queen's Bench do? It alleges as the chief reason for denying me its protection that I had taken the law into my own hands by this defence which I made in the House of Commons, so that, because I would not hear a foul libel against me repeated without a word in reply, I am denied justice in the highest court in the kingdom. Well, the Chief Justice complains that I did not call the medical witness who had attended White. Now, White had been flogged twenty-six days before his death, and had been taken into the surgical ward of the hospital, and very properly, because it was a surgical case—they had made it so by inflicting a wound; he was taken into the ward, and kept there for twenty-five days; but when his legs and bladder were paralysed, he was taken in that helpless state, against his own wishes, into the medical ward, to make it appear that he had died, not from a wound, but from internal disease. No attempt was made to deny this at the inquest, and I could not call that witness safely who had attended the deceased under the circumstances. What did Lord Denman say? He said that that medical officer was placed in a most perilous position. Lord Denman stated that, if that witness had stood by and seen too much punishment inflicted on White so as to cause his death, he would have been responsible for such loss of life; and yet that is the witness whom I should have first put into the box! A man who may be liable to a charge of murder is to be put into the witness-box, to give his testimony to the jury! I consider that for the sake of truth, for the sake of the jury, and for his own sake, I ought not to have placed him in such a position. I am satisfied that no one could have more misstated the law than Lord Denman has done in this case, and it remains the duty of an inferior coroner to correct the mistakes of the chief coroner of this kingdom.

Then there are two other medical witnesses, officers who had come down from London to examine the body. And now, observe, the law provides that, if any medical witness examines the body without the authority of the coroner, he shall not be paid the customary fee—implying that it is against their duty to make such examination. But they did examine in a certain way: not having cut down on the muscles of the back and examined the spine, they came to a final conclusion and made their report, having made only a partial examination of the body. There was not evidence on which the jury could rely: having made a post-mortem examination, proceeding on an assumption which they did not wish to disturb—that the deceased died of internal disease. I know that in the course I pursued I gave great offence, but it was not the first time, nor has it been the last. I gave offence because I adopted a line of conduct which led to the truth. It was disagreeable to some to hear the truth, and hence abuse and misrepresentation; but if I had not received that abuse I should have believed that I had not done my duty. Now, one of the medical witnesses said that he had never known a man die in consequence of a flogging; and if I showed abruptness to any one it was to that man. I speak as a medical man, when I state it as my conviction, that more have died from flogging in the British army than have perished in the whole country by the halter. I have asked, again and again, in the House of Commons, for returns of the names of the soldiers who have been flogged in the preceding year, and of the places where they might be found twelve months afterwards, but could never get them. The fact is, they know that the men have perished under the system. It is not long since a man was flogged at Brighton and died; the jury returned a verdict that the man had died of the flogging; it was taken no notice of, but passed off. There is nothing more dangerous to the constitution than an injury of the skin. At the very time the inquest was sitting, a footman in Russell-square received a slight injury, by burning his finger in attempting to extinguish a fire; he went to the hospital,

had it dressed, and returned to his duty; in forty-eight hours he returned, and in forty-eight hours after that was dead. This man, before receiving this injury, was in perfect health.

I remember holding an inquest on a child who was scalded by about half a tea-spoonful of hot water, which splashed out on her breast, producing a blister about the size of a half-crown, and from this slight cause she died in thirty hours. Add, if such are the results of causes comparatively trifling, what may we not expect from the lashing, the pounding, and the excoriation of the skin by flogging? The only wonder is, that more have not died than we suspect; and it is astounding that any man should have ever recovered the consequences of the injury; and it may well be characterized as a bloody, brutal, and disgraceful practice, and we must feel the utmost disgust for every one who uphold it. As I have argued on another occasion, they who would maintain it, as part of a wholesome discipline for the men, are bound, in justice to the junior officers, to see that they do not lose the advantage of it. The report which has been read shows that much good has been done by the inquest. During the last two years before this was held, 38,000 lashes were inflicted; and after it only 155 lashes in six months, or only five more for the whole army than on 'poor White. It is impossible that any one can reflect on these results without rejoicing; but I shall not deem the work complete until both these men are released from a service which they detest, and restored to us in the free exercise of their rights as citizens. As I have before said, the inquest was very troublesome. On the last day of its sitting I left my house at eight in the morning, and could not be home before five the next morning. It has been very expensive also: the law proceedings have involved very heavy expenses; but if not another shilling is subscribed for the liberation of these men, I will take care that the money shall be found. I have heard from persons who can, if necessary, employ their authority, that £50 will be sufficient to liberate both; and I trust that we shall soon have the pleasure of seeing both amongst us.

GOSSIP OF THE WEEK.

ALLEGED MISCONDUCT OF THE FACULTY IN BIRKENHEAD.

On Wednesday last, an inquest was held at Mr. Harwood's, Market Inn, before H. Churton, Esq., coroner, and a highly respectable jury, to inquire "how and by what means" the deceased, Caroline Gray, came by her death. From rumours as to alleged neglect by certain medical gentlemen, an unusual interest was excited; and, during the whole of the investigation, a great number of the profession were present.

The first witness called was Myre Tyrell, who stated that she had been in attendance on the deceased up to the time of her death. "She was first called in by the deceased on Monday, February 22nd, to attend her, as she was very ill, and fancied that the pains of labour were coming on. I then advised her to send for a medical man. I afterwards left her in the hands of a midwife, at about nine o'clock the same evening. Mr. Foulkes, surgeon, visited her. I saw him in the room: he had examined her. He immediately said to me, 'You see that this woman's time is come; but I can't attend unless I am paid one guinea. She will be delivered in about two or three hours, if she has proper attention.' He then immediately left; at the time of his doing so the pains were strong upon her. I saw her again between four and five o'clock the next morning. The midwife had also gone out for a short time. The deceased desired me to examine her. I did so, and found her in strong labour. The midwife told me that she had been so since three o'clock. The deceased urged me to go for a doctor, or she should be lost. I then went for Dr. Vaughan. This was about five o'clock. Dr. Vaughan stated, that having a

violent cold, he could not attend, but he sent me to Dr. Schofield, who, after some parley with his servant, at the door of his room, discovered that he also had a sore throat, and could not go. I afterwards went to Dr. Vaughan, and stated that Dr. Schofield could not go; but the only answer I got was from a person from the upper story, saying it was all well. I then called upon several other medical men, but could not get any one to attend. I then went to the Town-hall, and was referred by the policemen on duty to the parish doctor; but, having been there before, I did not go again. It was about half-past six when I returned. The deceased was very much excited and disappointed at my not bringing a medical man. Her husband then sallied out, and brought Mr. Steele with him. They arrived about nine o'clock. After Mr. Steele had examined her, he stated that she was in a very bad state: "the child ought to have been born hours ago." He also stated that his charge was "one guinea," and that he must be paid before he could do anything. When this was stated there were other persons present. I then went to fetch the husband, and upon my return I found Mr. Steele on the outside of the house apparently with the intention of leaving. He (Dr. Steele) remonstrated strongly with the husband for telling him from home, without being able to pay him. After some delay an arrangement was made about the fee. He returned into the house, and used the necessary exertions to relieve the patient. Finding he was not able to effect this, he went for Mr. Stevenson, with whom he held a consultation, after which Dr. Stevenson delivered her. The child was dead. She appeared to be doing well. Mr. Steele again called upon the Wednesday, and saw the deceased who had been rambling in the morning. He also asked the husband for his fee, but got none, upon which he stated that he should not attend again, although there was danger, unless he was paid. He then left. There was no medical man from Wednesday until Saturday, neither had she any medicine except a little castor oil. She was delirious at times. On Saturday I succeeded in getting a ticket for the Dispensary, but was told by Mr. Steele that there was no relief of that sort there, but he recommended me to the parish doctor, who was out of town. I afterwards got his assistant, who called and administered some medicine as well as relief. Dr. Vaughan called upon Sunday; she was then in a rambling state. He stated that there was no danger, and ordered me to go on with the medicine. About ten o'clock, the same evening, she slept. On the Monday I again saw her, when she was delirious. I sent for Dr. Vaughan, who came about ten o'clock, and requested, above all things, to keep her quiet. He also appointed a nurse to attend her. About six o'clock, I observed a great change; her pulse was very feeble, and a cold perspiration broke out upon her. Shortly after she died.

Dr. Steele and Dr. Foulkes then put several questions to the witnesses as to there having pointed out where gratuitous relief was to be had, but it did not appear that they had at all given them distinct information.

Dr. Stevenson was then called. He confirmed the evidence of the midwife as to the state of the patient, and also stated, in answer to a juror, "that he thought if medical aid had been properly rendered on the previous night there would not have been any difficulty." In answer to a question, he also stated that if he had found her in the state as first described he would not have left her.

This closed the evidence.

Dr. Steele here stated, that after attending the deceased up to Wednesday, and giving her friends all instructions necessary to get the assistance of the parish officers, he left her going on in as favourable a way as could be desired, but from some cause or other this advice was not acted upon until Saturday.

The jury then retired, and brought in the following verdict:—"That the deceased died

from puerperal mania, or childbirth; but the jury cannot separate without expressing their regret that more prompt and efficient aid was not rendered by the medical men in attendance on the deceased; at the same time they beg to thank Mr. Stevenson for his prompt attention to the deceased when called upon to do so."—*Liverpool Journal*.

MEDICAL REFORM.—In a letter addressed to the local secretaries the National Institute make the following statement:—"It affords us much pleasure to enclose you a copy of a memorial, addressed by the Council of the National Institute to the Right Honourable the Secretary of State for the Home Department, and to inform you that, since that memorial was presented, a deputation from the council has been favoured with an interview by the Right Honourable Sir George Grey, and we feel justified in stating that the result of the conference between the deputation and the representative of the Government was highly satisfactory to the claims and prospects of the general practitioners of this country. * * * In the year 1844, when the agitation induced by the Government bill of that date commenced, the general practitioners of this country as a class, were in a totally unorganized state;—associated with the physicians and with the fellows of the College of Surgeons in the various local societies throughout the kingdom, they were in danger of becoming parties to a measure which, so far as their own class was concerned, would have been inimical to their interests and derogatory to their position as a scientific body. The tendency of the bill in question was fortunately discovered; the manifesto issued by the Medical and Surgical Society of the borough of Marylebone placed it in a clear point of view, and the National Association of General Practitioners was commenced and most effectually organized. Between four and five thousand members of the profession could but obtain a hearing on the part of the Government. The result was an abandonment of the first Government bill, and various attempts to overcome the difficulties by a compromise. The representatives of the National Association adhered to the interests of their class, and to the public interests as identified with those of the general practitioners; the Government would not proceed without the concurrence of the colleges; the bill was amended three times successively, and was ultimately withdrawn. Thus, Sir, the general practitioners, by their representatives at the seat of Government, successfully opposed, the power and influence of the colleges. The bill of Sir James Graham was originally intended as part and parcel of a system of legislation which commenced with the unjust charter granted to the College of Surgeons, and was to have been followed by a charter to the College of Physicians having a similar tendency as respects the general practitioners,—thus rendering complete the two first portions of this legislative scheme. These events have proved that the general practitioners united, when they have justice and truth on their side, are strong enough to make an efficient stand against all their opponents. They have prevented aggressive legislation, and they might probably force upon the Government and the Legislature such a reform as the circumstances of the profession and the public now demand—but for this end they must be united as one body. Disunited, and without an authoritative head, they would assuredly sooner or later lose their present social and professional position, and be assimilated, in the eyes of the public, with uneducated pretenders to the healing art. The National Association was essentially ephemeral in its character. It took its rise during the excitement of the period, and it ceased to progress when that excitement subsided. Hence the necessity of forming the National Institute of Medicine, Surgery, and Midwifery. The great aim of the promoters of that Institute is permanency—that the general

Practitioners may have a representative body continually at its post, until the legitimate objects of the class thus represented are fulfilled—willing and prepared to perform these duties—active and passive—for any period, and under every emergency which may arise in the progress of a great public cause. It was the desire of the Committee of the National Association that we should thus remind you of the present position of the General Practitioners; and, if you concur in the views of the committee, that we should request you, in their name, to use your best exertions to further the efforts of the committee in establishing the National Institute upon a solid and permanent basis; and as the Association can only be brought together upon some great emergency, similar to that from which it took its rise, we are also requested to request you, to state to the Members of the National Association, that their committee have every confidence that the objects of the Association will be kept steadily in view and actively promoted by the Council of the Institute—the power and influence of which must, however, necessarily depend upon the support which it meets with from the great body of General Practitioners of the Kingdom. We beg further to inform you, that by a resolution of the committee, the balance of the funds of the Association, amounting to £67 17s. 7d., has been handed over to the treasurers of the Institute, for general purposes, and that, all liabilities having been discharged, the donation list of the Association is at present closed.

In an action tried at Swansea, Mr. Chilton, Q.C., in his address to the jury, spoke as follows, according to the *Swansea Times*:—"Now, he would tell them a significant fact of the evil resulting from giving inadequate damages. In an action brought by Mr. Wakley against the *Medical Times* for a libel, the jury gave £150 damages; and it was calculated that, in reporting the trial, the libel was reprinted in a greater number of papers than £150 would pay for, if the same libel was advertised."

THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—The officers for 1847 are as follows:—President—James Moncrieff Arnott, F.R.S.; Vice-Presidents—Robert Ferguson, M.D.; Jonathan Pereira, M.D., F.R.S.; Robert Liston, F.R.S.; Richard Partridge, F.R.S.; Treasurers—George Burrows, M.D.; Benjamin Phillips, F.R.S.; Secretaries—George Cursham, M.D.; Fred. Le Gros Clark. Librarians—William Haly, M.D.; Richard Quain, F.R.S. Other members of Council—George Budd, M.D., F.R.S.; W. F. Chambers, K.C.H., M.D., F.R.S.; P. N. Kingston, M.D.; Thomas Mayo, M.D., F.R.S.; James Arthur Wilson, M.D.; Henry Ansell; Richard Blagden; George Busk; Charles Hawkins; Benjamin Travers, F.R.S.

Mr. Hodgson, of Northallerton, suggests to us another form of portable inhaler:—"The inhaler is a quadrangular vessel, made of tin, divided into three compartments by two partitions, which are covered upon their upper surface with flannel, and are soldered (air-tight) along their sides and one end only; between the other end of the vessel and the inhaler there is a space large enough to allow of a free passage to the air during respiration. The position of the spaces is shown in the diagram. Upon the top of the inhaler, and at opposite ends, are two stopcocks, marked A and B; through A is poured the ether, which, in passing to the bottom of the vessel, passes over and completely saturates the flannel, the surplus remaining in the lower compartment. The ordinary flexible tube, furnished with the respiratory valves, is screwed into the stopcock marked B in the drawing. When used the two cocks are opened; the course of the current of air during each inspiration is pointed out by the direction of the arrows. The ether easily passes into the upper part of the apparatus; and again, by its descent, flows over the flannel."

Mr. GILMANIAN, the secretary of the Patent Epithem Company, contradicts the statement of the *Brixton* correspondent by informing us that

"the epithem-plaster has not been sold at Brixton for years; but prices have fallen in deduction to those disastrous of recent date. The numerous opinions," he adds, "the company continues to receive from men of the greatest professional eminence"—a fact to which we can bear witness—"is highly satisfactory."

SIMPLE AND EFFICIENT LITHOTOMY.—Dr. Beattie, of Tewkesbury, sends us this suggestion:—"Fit, by means of a cork, the stopper of a bladder's common pump, in the center of a Bourge's inhaler, and then, fixing the tube of the Bourge's inhaler in the upper orifice of the edema pump socket, use it as an inhaler. If it be found that the leaden valve of the pump is too heavy, it may be taken out and replaced by wire of sealing-wax. A couple of ounces of ether may be put into the inhaler, and the inhaler placed in hot water, the nose being closed, it is regulated by a small napkin, but not at the commencement of the operation. The slight access of air which the inhaler allows diminishes irritation and renders respiration easy, whilst the side valve carries off the expired air and preserves the vapour pure."

Dr. Merrihan, having resigned the office of physician to the Westminster General Dispensary, has been appointed consulting physician to the charity; and Dr. Wegg, of Maddox-street, has been elected to the vacancy.

Dr. Hilbers having written—"There is not a civilized country under heaven that is not illuminated by its beams, and even on the inhospitable western coasts of Africa it has extended the sting from that fatal fever which has hitherto defied all human means which have been tried to conquer it,"—a correspondent wishes, through your columns, to ask where he may obtain information confirmatory of the paragraph alluded to. Having for a quarter of a century resided in climes where fever rages with the direst effects, he naturally feels interested in the subject. [We must add that our own interest in the question is not less than that of our correspondent's.]

APOTHECARY'S HALL.—Gentlemen admitted members March 11:—John Shepherd Fletcher, Thomas Oldacres, Thomas Binford Byrne, Nathaniel Best Gill, George Booker, Edward Mawthill Tearne, Horatio Sillifant, Charles Henry Holman, and Edward Hancock.

Ellis Fliccroft, agent for the sale of "Dr. Coffin's medicines," was charged at the Borough Court, Bolton, recently, under the statute 55 George III. A penalty of £20 is enacted against persons infringing the provisions of this act. The offence is also indictable at common law as a misdemeanor. It was proved that the defendant had sold medicines, particularly in the case of George Greenhalgh, upon whom an inquest had been held; and the defendant was ordered to find sureties to answer the charge at the quarter sessions.

The number of students in the French schools of medicine is about 1800, 800 of whom are in Paris.

MEASLES AND SMALLPOX IN BELGIUM.—Measles and smallpox are at present committing great ravages in some of the towns of Belgium. In Liège, during the month of January, there were 300 deaths.

In the Bengal Presidency, in 1844, the ratio of ordinary deaths to the strength of the corps was—as regards Europeans, 5.76 per cent., and, as regards natives, 1.17 per cent.

WAR-OFFICE, March 6.—3rd West India Regiment; Henry Shearly Sanders, gentleman, to be Assistant-Surgeon, vice Woodman, appointed to the 46th Foot. 48th Foot: Assistant-Surgeon George Thomas Woodman, M.D., from the 3rd West India Regiment, to be Assistant-Surgeon, vice Dickson, promoted on the Staff. Hospital Staff: Assistant-Surgeon James Dickson, from 48th Foot, to be Staff-Surgeon of the Second Class, vice Godwin, deceased.

OBITUARY.—On the 3rd inst., at his residence in Piccadilly, Dr. Adam Black, formerly of Sloane-street.—Dr. Cattereau, the assessor of Ruffell, has recently died in Paris. In December last, at Rio Janeiro, M. Felix B. de Azevedo, one

of the distinguished physicians of the Empire, Governor of Amazonas, died of the plague of Brazil, which he brought from his own country, where he was in his apartment. Feb. 24, at London, aged 67 years, John B. Montgomery, Esq., M.D., F.R.C.S., of Dublin, &c., &c., Feb. 25, aged 55, at Indian pectoria, George G. Pompey, Esq., M.D., of Fishponds, Bristol, long a member of the Provincial Medical and Surgical Association, and president-elect of the Bath and Bristol branch. Dr. Pompey was possessed of considerable scientific attainments, especially in his own branch of the profession—the relief of mental disease. The late Dr. Labbeek, of Norwich, was the younger son of R. Labbeek, Esq., M.D., who practised with celebrity in that city. His early education was received at a free grammar-school, under the late Rev. Edward Valpy. He commenced his medical studies under the late Dr. Scrimshire of Peterborough, and subsequently became a student at City's Hospital. He afterwards went to Edinburgh, where he became a dresser for two years to Mr. Liston. After passing his degrees as M.D. there, he became a member of the Royal College of Surgeons, London, and commenced practising in Norwich as a physician. Upon the resignation of Dr. Yelloly, as one of the physicians to the Norfolk and Norwich Hospital, Dr. Labbeek was elected to that situation; and, on the death of Dr. Wright, Dr. Labbeek was elected as the physician to the Norwich Bethel. During the last twelve or fifteen years, of more than 300 important cases in surgery were treated by him, from eighty to a hundred of which were for lithotomy, an operation which he performed with a success equal to that of the late Mr. Martin, whose name stands, at the present day, as the most successful of lithotomists. He was only forty-four years of age when he died. On Wednesday, the 3rd inst., at St. Helen's, aged forty-nine, William Garton, Esq., M.D., &c., &c., On Friday, the 12th inst., at Lea-park, Blackheath, Lawrence Hay Pyffe, Esq., M.D.—March 7, at Elm-cottage, Torpoint, in the twenty-eighth year of his age, from disease contracted after more than three years' service on the coast of Africa, N. Barrie Alexander, Esq., Assistant Surgeon R.N.

MORTALITY TABLE.

For the Week ending Saturday, March 12, 1847.

Cause of Death.	Total.	Average of 5 Winters.
ALL CAUSES.....	1026	1068
SPECIFIED CAUSES.....	1024	1061
Zymotic (or Epidemic, Endemic, and Contagious) Diseases.....	128	163
SPORADIC DISEASES.		
Dropsy, Cancer, and other Diseases of uncertain or variable Seat.....	106	112
Diseases of the Brain, Spinal Marrow, Nerves, and Senses.....	178	170
Diseases of the Lungs, and of the other Organs of Respiration.....	368	384
Diseases of the Heart and Blood-vessels.....	48	52
Diseases of the Stomach, Liver, and other organs of Digestion.....	76	70
Diseases of the Kidneys, &c. Childbirth, Diseases of the Uterus, &c.	12	12
Rheumatism, Diseases of the Bones, Joints, &c. ...	16	7
Diseases of the Skin, Cellular Tissue, &c.	64	2
Old Age.....	64	81
Violence, Privation, Cold, and Intemperance.....	48	80

a dozen, their novelty would make up for numerical deficiency, and they would form the basis of a pathological law. Any exceptions to this he would consider to weigh nothing against the grand point his first observations had tended to establish.

I cannot help thinking that some such mental infirmity as this, or the above I mentioned, must have possessed the prejudiced contenders for the local origin of fever. At any rate they cannot all be right, though each is ready to make oath that he is; if the truth be amongst them, only one can claim it, and that claim must be established at the expense either of the integrity or the intelligence of all the others.

It has always been to me a mystery that the individuals in question should never be able to meet with proofs against their particular doctrines. The man who has determined that fever shall arise from a morbid condition of none other organ than the brain, can never see anything in the bowels to indicate that the origin might have been there; the patron of *gastro-enteritis* never finds, within the cranium, one who has died of fever, any cause for this; and the lover of liver complaints is astonished that other pathologists cannot discover what has always been revealed to his visual sagacity—that the biliary organ is alone at fault in all cases of fever.

It happens, on the contrary, that pathologists who go to the bedside, and into the dead-house—divested of idle prejudices and conceits, prepared to search for the truth, and to take its several evidences as they may be manifested, whether uniformly or variously—discover no constancy of organic lesion in cases of fever. In one series of these, the cranial contents are seen to be exclusively morbid—in other series, the pulmonary apparatus is found to be chiefly abnormal—in other, the gastric—in other, the gastro-intestinal—in other, the biliary, and so on. But whether in these several examples, the fever were a *cause* of the organic alteration, or a *consequence* of it, is a point only to be determined by each individual case being minutely investigated and studied in all its bearings. But, assuredly, the most likely man to arrive at the *truth* of these things, would be he who had no prepossessions or prejudices to gratify, who was really a *truth-seeker*, contented with whatever facts might fall before him, and with whatever conclusions such facts might favour.

It not unfrequently happens, again, that fever runs a fatal course without any particular function being much deranged during life, or any organic lesion being discoverable after death. In your practice of last year you saw several examples. These are cases with which the symptomatologist contends against the doctrine of the exclusive pathological school. Now, it is more than probable, that there is *never* any alteration of function without alteration of structure, also; and that, in the instances above referred to, there was some organic change not cognizable to the unaided senses. The late researches of the microscope and of organic chemistry are suggestive of this opinion. Nevertheless, the symptomatologist is perfectly right in refusing to lend his credence to this assumption, or the other, of the pathological school, and in maintaining his own belief, until demonstrative evidence shall prove that he is wrong. And the success of his simple, unspecific form of practice proves that he can afford to wait, without detriment to his patients, until the pathologist shall bring undeniable proofs of organic lesion being the origin of simple fever. As I have said, my own reflections incline me to the belief that such proofs will one day be given; but at least we do not possess them at present; we must not permit them to be assumed; and it will be time enough to substitute a new form of practice for the old one, when it can be shown that, in making such experiments, we are incurring no sacrifice.

I have dwelt thus far upon this topic, to show the absurdities of undue theorizing in medicine; and to suggest to you how much wiser and better it is to accumulate and apply useful facts, than to indulge an inclination for idle

To turn, now, to the practical part of our subject. You will always find, during the prevalence of epidemic fever, in even the simple form in which it occurred in this neighbourhood last year, that certain cases of it will exhibit peculiarities dependent upon the particular condition of the subjects at the time of their attack. The fever is apt to derive some character from the state of health of the individual at the period of seizure. If any organ be the subject of disorder, this is likely to be increased by the superintention of the fresh ailment, and to impart to the feverish symptoms a more specific character than they would otherwise have possessed. This was especially the case with the fever of last year. Amongst the poor who suffered from the effects of starvation, and were in a state of cachexia, the fever presented chiefly typhoid features; in others, reduced from insufficiency of food, but still with impoverished, rather than depraved, states of body, a gastro-enteritic condition was the leading organic trouble; in others, dyspeptic from over-indulgence, or the use of indigestible food, the stomach alone suffered, the bowels being comparatively easy; in plethoric subjects, liable to determination of blood to the head, cerebral congestion and stupor marked the progress of the fever; in such as had previously laboured under bronchitis, pulmonary congestion became the concomitant of the febrile state; in those suffering from liver disorder or disease, the fever had a striking bilious type; when it occurred to people in average health, it presented the symptoms I described in my last lecture; when to others of vigorous constitutions and active habits, and in florid health, its symptoms were chiefly those of inflammatory fever. We really had, then, prevailing at about the same time; what some authorities, fond of localizing fever, would consider the following forms of it—typhoid; gastro-enteritic; gastric; cerebral-congestive; pulmonary-congestive; bilious; low nervous; and inflammatory. There can be no doubt of each being both symptomatologically and pathologically different from every other; but this difference was owing, as I have said, to the particular condition of the patients at the time the fever attacked them. The fever did not wander about, here typhoid, there gastric, and elsewhere bilious, and so on; it was the same, the town and neighbourhood through, except in so far as it received a modification in certain of the subjects it visited. I will give you some illustrations, corroborative of what I say.

Eliza Scandret was admitted into the hospital, under my care, at the latter end of December last. She had been the subject of fever, three or four days prior to admission. When I first saw her, she complained of excessive lassitude, and of a sense of aching all over. She was very thirsty; had no appetite; slept indifferently, and started in her sleep; had alternate fits of heat and chilliness; constant nausea, and occasional vomiting; tenderness, on pressure, over the epigastrium and superior part of the abdomen; tongue furred and dry in the middle, and very red at the edges and tip; pulse 106, hard, and rather full. I learned that she had been the subject of indigestion, probably occasioned by confinement and indifferent food, during the three weeks prior to her entrance into the hospital.

This form of fever, you will perceive, differed from that in general, in the gastro-intestinal trouble that accompanied it, and that, in a minor form, had been its precedent. She was ordered the following:—℞. Soda bicarbonatis, tinct. hyoseyani, aa. ʒj.; acidi hydrocy. (Sch.), m. x.; mist. camph., ʒviij.; m. ft. mist. cujus cap. coch. ampl. duo tertis horis. The bowels were confined, and I prescribed this sharp mercurial purge:—℞. Hydrarg. chloridi, pulv. scammonii, aa. gr. ii.; m. ft. pulv. cap. stat. To have a mustard-plaster six inches square to the epigastrium, and the feet to be immersed in hot mustard and water at bedtime. On the following morning, she was somewhat improved, and this improvement continued during several following days, except that occasionally we had

an increase of fever or of gastro-intestinal irritation, which called for frequent febrifuges and counter-irritant treatment. At the expiration of the fifteenth day, she was only troubled with a sense of sinking at the pit of the stomach, in common with a feeling of general debility; she had no symptoms of fever; her appetite was regular but not good—that is, too little food satisfied her, though she wanted it at stated times. Her tongue was covered with a pale fur, moist, flabby, and indented at the edges. It was surmised that her chief ailment at this time was gastric debility. She was ordered the sixteenth of a grain of strichnine in solution three times a day, an occasional aperient, and nutritious food. She improved most satisfactorily under this treatment, and in a fortnight left the hospital well.

On the 4th of December last, we had a *post-mortem* of a girl named Morris. On the 3rd of the previous month, she was first attended by Mr. Carter, as a patient of the General Dispensary. Her chief symptoms then were lassitude, general aching pains, thirst, loss of appetite, and throbbing pain in the head. The pulse was hard and full, but not frequent; tongue furred; pupils slightly dilated; obscure pains about her bowels, which were not affected by pressure. Febrifuges every three hours, leeching to the temples, with mercurials twice a day, and aperients when needed, constituted her treatment. She improved for some few days, and then relapsed, and seemed to become hysterical, when Mr. Carter gave her ammonia, under which she rallied for a time, but again relapsed, and then I was requested to see her. I found her pale, but not emaciated; pupils dilated, and not sufficiently sensible to light; tongue coated with a brownish fur; pulse 104, thick, but not hard; skin soft, and bedewed with plentiful perspiration; excessive languor; bowels costive and tumid; great feeling of weight and throbbing in the head; occasional incoherence.

I learned that, for some years past, she had suffered from frequent pains in the head, unconnected with any obvious disturbance in the digestive or uterine function. She was in the habit of sleeping very soundly and snoring at night, and of often falling asleep during the day.

Considering this cerebral oppression, therefore, as not a recent occurrence, and judging from her pulse and feeling of prostration, I thought it not expedient to order even local bleeding. A blister was applied to the back of the neck; a dose of calomel and scammony was administered, followed, shortly, by a turpentine enema. I suspected passive congestion of the brain, and preferred to treat it, for the reasons I have mentioned, by counter-irritant, purgative, and derivative means, rather than by direct depletive ones. I was not able to visit her the next day, but she was reported to me as somewhat improved. I saw her the day following, and found her in so unsatisfactory a state, and surrounded by so few domestic comforts, that I advised her removal to the hospital. It was not until the day after this, that she was conveyed thither, and then she appeared to me to be sinking. Her surface was pale, cold, and clammy; pulse 80, full and soft; she was only sensible when roused. Hot-water bottles were kept constantly applied to her feet; a mustard-plaster was laid over the epigastrium and region of the heart; and ammonia and camphor with wine were administered at due intervals. She gradually sunk, and died in twenty-four hours after her entry.

Post-mortem.—The lungs were quite natural in aspect and feel. The heart was, curiously enough, quite empty throughout. You remember my remarking to you, as I opened its cavities, that each one was as clean as though it had been washed and dried. I never saw such an appearance before. The left ventricle of the heart was very firm, red when incised, and hypertrophied; its walls were nearly an inch in thickness. The right ventricle and auricle were pale and thin, and considerably dilated; the auriculo-

ventricular opening was more patent than natural. There was a little fluid effusion into the superior portion of the spinal cavity. The surface of the brain was congested throughout, and in some places there was a very small quantity of lymph effused. About two ounces and a half of clear serum were found in the left ventricle of the brain, and about half an ounce in the right. The substance of the organ was generally more vascular than natural, and in spots was very slightly softened. The peritoneum was quite free from vascularity, but was adherent to the intestines in places, and covered with minute granulations, bearing somewhat of a tubercular appearance. The other viscera were natural.

The condition of the peritoneum was evidently recent, and therefore had nothing to do with her immediate illness. The peculiarity of her heart was particularly favourable to congestion of the brain. There was the hypertrophied left ventricle, driving its blood with unusual impulse, and, as a matter of course, the current along the carotids would be proportionately strong, and the arterial condition of the brain would correspond; then, there was the dilated state of the right side of the heart, with patency of its auriculo-ventricular opening, favouring regurgitation by the superior cava, and thus causing venous congestion of the brain. There were two sources, then, whereby this organ suffered from too much blood: one increasing the quantity sent, the other preventing a due return. Hence the oppressive headache, sleepiness, and stupidity, under which the poor girl had for some time laboured. Fever, occurring under such circumstances, would be most likely to mark itself by an increased disturbance of the already suffering organ. It did so; and she died from congestion of the brain, and the serous effusion consequent upon it.

You remember the man who left the middle male ward, convalescent, about a fortnight ago. I forget his name at this moment. He came in the subject of simple fever, supervening upon liver disorder. I remarked to you, particularly, the state of his complexion, urine, and faeces. Additionally to all the ordinary symptoms of fever, he had a dingy-yellow complexion, tenderness of the right hypochondrium, and dulness on percussion over a larger extent than natural. He vomited bile and frothy mucus frequently, and occasionally dark matter like coffee-grounds. He had suffered from fever for about a fortnight; his liver disorder had existed several weeks. Off the African coast, he would have passed very well as the subject of a mild form of yellow fever. He was very prostrate, and, therefore, we gave him ammonia, with carbonate of soda and nitric ether, in camphor mixture, every three hours; a calomel and rhubarb purge at once; and moderate doses of grey powder, night and morning; also, counter-irritation over the region of the liver. We had some little trouble with this man, and for a few days I felt apprehensive about him. At last, however, his motions became of a proper colour, he made plenty of water, perspired freely, and lost his sickness and pain in his side; his complexion also became much clearer. We then suspended the mercury, gave him vegetable bitters, with soda and hydriodate of potash, and put an ammoniaco-mercurial plaster upon his right side. He continued thus for a fortnight, and was then dismissed well.

DUMAS ON ORGANIC CHEMISTRY. No. XV.

ON THE URINE.
(Continued from p. 72.)

Pathological Urine.—In most diseases, the urinary secretion is more or less modified. It may be augmented in quantity, or it may be diminished. Its density, its odour, its colour, the materials which it contains, and the sediments which it throws down, may all vary to a greater or less extent. We know that the ancients attached great value to the examination of these variations, which formed a very important ele-

ment in the appreciation of the symptoms, and more especially of the progress, of certain diseases. But since more positive symptoms, based upon a better knowledge of the laws of physiology, have succeeded to that empiricism with which medicine used to be so much encumbered, the appreciation of the characters of the urine has, in a great number of maladies, lost that exaggerated importance with which it used to be invested. In truth, both numerous and extended researches have been made as to the composition of the urine in disease; but these analyses have, in but very few cases, led to decisive consequences, or to such as possess any real value for the physician and the physiologist. There is nothing astonishing in this result.

The study of the alterations of the urine is beset with difficulties. When the system is once imbued with the malady, so many circumstances may arise to influence the urinary secretion, that it is in many cases extremely difficult to allot to each its just value. Thus, the augmented or diminished activity of the respiration, the abstinence from food, the drinks and medicines administered, the perspiration which may be developed, are all so many conditions capable of modifying the qualities of the urine. Observers have not always made due allowance for these facts, and hence, probably, the reason of their researches remaining so imperfect and sterile in general results which could be of value to science. We will, however, here briefly indicate the results of the most careful analyses, and point out the best drawn characters of pathological urine.

In inflammatory diseases, the urine is in general of a deep colour, sometimes of a brownish red or perfectly brown, and possesses considerable density. The proportion of urea varies: most frequently it is augmented; sometimes, however, it is diminished, as invariably happens after copious venesection. The uric acid, on the contrary, appears always to augment, and in some cases is found as high as 3 per cent., or even, according to M. Becquerel, 5.9 per cent., when compared to the weight of the solid materials; whilst, in normal urine, it only attains the proportion of 1.5 per cent. As to the salts, they are always diminished—a fact which is explained by the influence of the diet imposed on persons in a state of disease. According to the observations of M. Simon, however, the sulphates form an exception to this rule,—being rather augmented than diminished,—which is readily accounted for, inasmuch as the sulphuric acid of the urine results in great part from the oxidation effected on the sulphur of the albuminoid matters, under the influence of respiration, which, as we know, is rendered very active in inflammatory diseases. The existence of sulphates in the urine is then, up to a certain point, independent of the quantity of solid elements introduced into the system.

In the last stage of inflammations, as in a great number of other diseases, and especially in intermittent fevers, the urine throws down a sediment. Most frequently these deposits are of a dark yellowish colour, and are formed in part by uric acid or by the urates; sometimes they consist of mucus, and more rarely still of the insoluble phosphates. In the latter case, the urine is invariably ammoniacal.

This reaction appears to be occasionally manifested in the urine of patients affected with low fevers, as typhus, &c., and is perhaps owing to a too-prolonged stay of the urine in the bladder. However this may be, the other characters of the urine are remarkably modified under the influence of these grave affections: it is usually found to be of a brown colour, and is specifically lighter than normal urine; its urea is always diminished; so also, with regard to the salts, without excepting even the sulphates. The uric acid, alone, is often augmented in proportion.

In the first stage of phthisis, the urine frequently presents the same characters as in inflammatory affections; it is more coloured and denser than in the normal condition; and this state of concentration augments still further,

when, towards the end of the disease, the nocturnal sweats and colliquative diarrhoea become established. According to the observation of M. Becquerel, the quantity of urea secreted in a given time diminishes greatly, whilst the proportion of uric acid is very notably augmented, sometimes rising as high as five per cent. compared to the solid residue. This circumstance is easily explained. For, sanguification no longer being perfectly accomplished, the formation of products, less oxidized than urea, becomes as a consequence more abundant.

In dropsy, the composition of the urine undergoes remarkable changes: it generally contains large quantities of albumen, which may be discovered with ease by adding to the urine a few drops of nitric acid. In albuminous nephritis, or Bright's disease, the urine becomes charged with so large a quantity of albumen that it coagulates in one mass by heat. The urea is greatly diminished in the urine, in these cases, whereas its presence may be with facility recognised in the blood. In the active stage of this disease, the urine acquires a red or brownish-red colour, and by rest throws down a deposit of brown flakes formed of fibrine and of blood-globules. This fluid presents an analogous alteration in inflammations of the bladder, and under the influence of copious hemorrhages. Should the blood-globules exist in their natural state in the urine, they will usually be found deposited at the bottom of the vessel. In this case, they may be easily perceived by the aid of the microscope. But it often happens that these globules have become so altered as not to be recognisable, or else that the colouring matter of the blood exists in the urine in a state of solution; we must then endeavour to effect the isolation of this principle by causing its coagulation by heat; under these circumstances, it separates in the form of brown flakes, which are subsequently to be treated by sulphuric acid and alcohol.

In some cases of hematuria, the urine is found to be so loaded with the principles of the blood, that, when abandoned to itself, it coagulates spontaneously and forms a true blood-clot.

In the last stage of inflammation of the urinary organs, and especially towards the end of albuminous nephritis, when the kidneys begin to be disorganized, we often meet with pus in the urine. The puriform globules may be readily distinguished by means of the microscope.

In icterus, the urine always presents a brown colour of more or less intensity, which is owing to the presence of the colouring matter of the bile. Nitric acid causes in this urine some characteristic changes of colour, of which we shall have occasion to speak when treating of the nature of the bile.

The composition of the urine undergoes a remarkable alteration in the disease, known as diabetes mellitus. This change consists in the presence of a greater or less amount of glucose. The patients are tormented by an insatiable thirst, and go on passing quantities of urine proportioned to the amount of drink which they take. Generally speaking, the quantity of urine excreted varies from 5 to 10 litres (a) in the day; but, in some cases, it has reached as high as 25 litres. Numerous researches have been made upon diabetic urine; but observers are not all agreed as to the results. Some have affirmed that the absolute amount of urea and of uric acid is diminished, and that these principles may even altogether disappear. On the other hand, it would seem to result from the experiments of MM. Gregor and Kane, that the total quantity of urea excreted, during twenty-four hours, is not inferior to the normal proportion, and in some cases may even exceed it. Only, as it is found diluted with a larger quantity of water, the richness of the liquid in urea must diminish, according to the quantity of urine voided in a given time.

M. Lehmann was the first to point out the

(a) The litre is equal to a French pint, or about one English quart.

existence of hippuric acid in diabetic urine. It appears that, at the commencement as well as at the termination of this disease, the urine contains a certain quantity of albumen. It has, moreover, a lightish colour, and is frequently thick, and denser than ordinary urine: it is, as already stated, characterized by the presence of glucose, which communicates to it the property of deviating the plane of the polarization of the light towards the right. The apparatus of M. Biot is a very convenient one for proving the presence of this principle, and is certainly capable of rendering great service in the diagnosis of diabetes.

To isolate the sugar from the urine, we commence by evaporating this liquid in a water-bath to a syrupy consistence. The residuum is treated by boiling alcohol, of a specific gravity of 0.833, until nothing further is taken up by this menstruum. The alcoholic solutions, being in their turn evaporated to a thickish consistence, and left to themselves in a cool place, crystallize in the course of a few days. These crystals are to be purified by the ordinary methods, when they will be found to possess all the characters of glucose. Diabetic urine owes to the sugar which it contains the property of fermenting on the addition of yeast. Globules of ferment are even spontaneously developed in it. Fermentation offers then a good means for discovering the presence of sugar in the urine; but, when we make use of beer-yeast to excite this action, we must be careful that the latter does not ferment of its own accord; to guard against this, we have merely to wash it several times in water. By heating the urine of diabetic patients after adding to it a few drops of potash, it becomes of a more or less deep brown colour, in consequence of the alteration of the sugar which it contains. This mode of proceeding was proposed by M. Mialhe, and is both a quick and easy way of valuing the proportion of sugar.

Annexed are some analyses of diabetic urine made by MM. Simon and Bouchardat:

	Simon.	Bouchardat.
	I.	II.
Density	1.018	1.016
Water	957.00	960.00
Solid materials . .	43.00	40.00
Urea	traces	7.99
Uric acid	traces	traces
Sugar	39.80	26.00
Alcoholic extract	2.10	6.60
Aqueous extract		
Salts		
Phosphates and mucus	0.52	0.80
Albumen	traces	traces
Oxide of iron (?) . .		0.14

What is the origin of sugar in diabetic urine? MM. Thenard and Dupuytren were the first to draw attention to this important question. M. Berzélius thinks that the neutral azotized matters of the economy become transformed into sugar. He believes that it is the same with the ingested azotized matters, and, according to him, patients fed on animal substances void an equally saccharine urine, as those who adopt a different diet. M. Bouchardat has arrived at totally opposite conclusions. He has shown that sugar is found in the blood, but not until some time after a meal, and that blood, when drawn in the morning, is perfectly free from it. He is led to attribute the presence of sugar in the urine to the amylaceous matters introduced into the economy: for, after a purely animal diet, he has constantly found the quantity of sugar diminish. His researches on this subject have led to the happy idea of compounding a bread almost entirely composed of gluten, the employment of which seems to have been attended with considerable advantage in several of the Parisian hospitals.

The name of *diabetes insipidus* has been given to a pathological state, characterized by an abundant discharge of urine, which is exceedingly poor in solid matters. This alteration of the urinary secretion is distinguished from diabetes, properly so called, by the absence of glucose, and by the urine being perfectly insipid.

We will now proceed to the study of some other alterations of the urine. Various observers have remarked a bluish coloration of this fluid, which has in some cases been attributed to Prussian blue. This appears to me, at the least, doubtful. Still, I have been able to verify the fact that cyanurets are occasionally formed in the economy. Thus, in the treatment of a wound formed by caustic potash, I have seen the linen which was used for dressing become quite blue: this was produced by the cyanurets, which escaped from the wound, coming in contact with iron, with which the linen had been accidentally soiled, and which thus gave rise to the formation of Prussian blue. I do not, however, believe that analogous phenomena can take place in the urine.

Braconnot has given the name of *cyanourine* to the blue matter of the urine of which we have been speaking. Cyanourine is a powder of an intense blue, without odour or taste; it is slightly soluble in water, to which it gives a brown colour by ebullition. The acids change this colour to a rose-red. It is somewhat soluble in boiling alcohol, from which, on cooling, it is deposited as a blue powder. The alcoholic solution possesses a greenish tint. The dilute acids dissolve it; the alkalis precipitate it from these solutions in the form of a blue powder. Nitric acid destroys it, and transforms it into *carbazonic acid*. When heated in a closed tube, it is in like manner decomposed, and gives out carbonate of ammonia, together with some empyreumatic oil, leaving a carbonaceous residuum behind. This blue matter does not always appear to offer the same properties. Spangenberg found it to be insoluble in hot water, boiling alcohol, boiling hydrochloric acid, and the carbonated or caustic alkalis. Boiling alcohol and ether do, however, dissolve it and colour it blue. So also with concentrated sulphuric acid; when dilute, it dissolves it but very sparingly. According to Granier and Delens, it should be soluble in water.

Granier, Delens, Proust, Braconnot, Spangenberg, Marcet, and others, have described a black kind of urine, more or less deep in colour. Proust has given the name of *melanic acid* to the black matter which he found in the urine. This matter is soluble in the alkalis, from which it is precipitated by acids. These solutions give brown precipitates with most of the metallic salts. Braconnot has denominated as *melanourine* a matter which he has found in the urine, after having separated the cyanourine from it by filtration; by heating the urine in this state, it precipitates a substance of so deep a colour that it appears black. Its properties are very similar to those of cyanourine.

Seminal fluid is sometimes met with in the human urine: whether it be that it is poured into the urethra in consequence of some involuntary seminal emission, or that it may arrive there by the efforts which often accompany the escape of the fecal matters, &c.; it may even flow back towards the bladder, and so become mixed with the urine, where there exists a stricture or narrowing of the passage below the orifices of the ejaculatory ducts. It is always easy to recognize the presence of seminal fluid by the animalcules which it contains: for this purpose, we have merely to receive the urine into a long and narrow glass tube: the animalcules, being specifically heavier than the urine, sink to the bottom; the fluid should then be decanted, and the deposit examined by the microscope; or else, the urine is to be passed through a filter, when we shall find the animalcules in the last drops of the liquid at the very point of the strainer. The absence of animalcules in the urine is, however, not always a proof of the absence of seminal fluid: for, in some affections of the genital organs, they are no longer met with in the semen. In old men, for instance, in place of animalcules we sometimes find shining globules, which have been mistaken for imperfect animalcules. The prostatic fluid may also be accidentally mixed with in the urine.

Normal urine always contains a small quantity of fatty matters. It appears that, in certain diseases, and especially in phthisis, the propor-

tion of fat in the urine may be augmented, and globules of this matter are sometimes found floating on the liquid. This is a species of alteration which may with facility be recognised by means of the microscope.

When urine, however, beyond the fatty matter, contains a certain quantity of albumen, it is denominated *chylous*. This urine is ordinarily thick, or even milky, and beneath the microscope it exhibits globules of fatty matter. The secretion of chylous urine almost always coincides with a peculiar alteration of the blood, characterized by the presence of a great excess of fat in this liquid.

Some observers have even insisted on the existence of milk in the urine. But, to remove all doubts on this head, it is essential that the materials of the milk should be clearly pointed out in this secretion, and demonstrated by precise experiments. The urine should, moreover, be so collected that there cannot be the slightest suspicion of fraud in the matter.

ORIGINAL CONTRIBUTIONS.

OBSERVATIONS ON URINARY CALCULI, AND ON LITHOTOMY.

By F. H. BRETT, Esq. M.D., F.R.C.S.
Member of the Royal Asiatic Society; late Surgeon to the Governor-General of India's Body Guard, and Government Ophthalmic Hospital, Calcutta.

(Continued from p. 77.)

Preparatory Treatment and Prognosis, &c.—Very different is the case often with the phosphatic diathesis, the attendant on a high degree of irritation, and sometimes connected with organic disease. It is truly distressing to witness the peculiarly severe suffering attending this form of the disease, the emaciation, the exhausted expression of countenance, the loss of appetite, and high degree of constitutional and local irritation, which, together with the appearance of the urine and sediment, so readily indicate this form of the disease; indeed, the looks of the patient in the severe forms are alone pathognomonic. These patients cannot be operated upon with safety until the treatment formerly detailed has been employed so as to allay the irritation. After the employment of muriatic acid, opiates, with hyoscyamus, suppositories, &c., have ameliorated the severe sufferings of the patient, and, where the system is not completely exhausted, it is truly delightful to witness the effects of the operation. The pain attending it is a matter of comparative insignificance to such subjects, and the instantaneous cessation from all suffering acts like a charm on the late unhappy patient, who generally convalesces with rapidity.

We cannot be too minute in this diathesis in inquiring after the existence of organic disease in the kidneys, or an ulcerated state of the bladder. Some unfortunate cases have presented themselves, in which it would be the height of impropriety to attempt an operation. A patient presented himself, at the Central Hospital, in Calcutta, labouring under all the worst symptoms of irritation and the phosphatic diathesis, there was likewise purulent discharge from the bladder. I declined operating, for which he was importunate, and adopted palliative treatment. The patient died shortly afterwards, and on examination there were extensive abscesses in the kidneys contained in cyst; the right one contained two large calculi of the triple phosphate in its pelvis. There was also another found in the bladder. The parenchyma of the right kidney was completely disorganized and adhering extensively to the surrounding textures. It was thrice its natural size. Both the ureters were distended with purulent matter. The coats of the bladder were thickened, and its external surface extensively ulcerated. A purulent discharge from the bladder alone is not, however, a sufficient objection to the operation, as successful cases have occurred where it existed; but it should not be attempted until the patient has undergone a careful preparatory treatment.

In the higher ranks of society, Europeans es-

pecially, in India, and among those who have lived luxuriously, or drank freely, and in the plethoric children of Europeans in tropical climates, the preparatory treatment must be particularly attended to in this, as, indeed, in all capital surgical operations; but here also the introduction of sounds, to accustom the parts to the irritation of instruments, as it is termed, is to be reprobated.

Mode of Operating.—Considering simplicity of instruments one of the first axioms in surgery, I generally employ nothing but a sharp scalpel, a straight staff, and forceps. A dose of castor oil should be administered on the previous night, and in Europeans an enema in the morning. In natives of India the rectum is almost invariably evacuated early in the morning, and, therefore, this precaution is not absolutely requisite. The circumstance should be ascertained by inquiry, and the empty state of the rectum clearly known by examination *per anum*, which also excites contraction. The vapour of ether obviates the necessity for an opiate previous to operating. The existence of the calculus, by sounding, is, in all ordinary cases, to be ascertained immediately previous to operation, both by the surgeon and assistants. Figures 2, 3, 4, 5, 6, are the instruments I always prefer.

The necessary apparatus, in addition to the instruments above mentioned, consists of a scoop, two or three sharp scalpels, a spring tenaculum, and several curved and straight forceps, of different lengths—bandage, lint, sponge, warm water, and oil. A Reed's syringe may be occasionally required, should the stone be soft and break under the forceps. If the operator anticipates a very large calculus, he ought also to furnish himself with a long, narrow, probe-pointed knife, and forceps capable of crushing the stone, if requisite. These are to be placed on a chair, to the right of the operator, and covered with a towel.

The patient is placed on a firm table, about two feet and a half high, with his head and shoulders well raised by pillars; and a low chair should be in readiness for the operator, whose breast should be in a line with the patient's abdomen.

The staff being introduced before the patient is secured, it is to be held steadily by an attentive assistant against the arch of the pubes, giving its handle such a degree of inclination towards the right side as shall cause the staff to be parallel with the ascending ramus of the left ischium. The hands and ankles being now secured by lithotomy garters of broad worsted tape, a bandage passed round the neck and under the arms, and the thighs separated and pelvis fixed by able assistants, the scrotum is raised by the other hand of the assistant who holds the staff, and the skin of the perineum is to be made tense by the surgeon's left thumb.

These preliminaries being completed, the first incision is to be effected with a very sharp double-edge scalpel, by a free bold incision, com-

mencing near the raphe on the left side; on a full-grown man, an inch and a quarter anterior to the anus, and, therefore, below or posterior to the arch of the pubis, terminating midway between the ischiatic tuberosity and anus, and below the inferior margin of that outlet, penetrating through the integuments, fat, and superficial fascia of the perineum. The second incision immediately following divides the transverse muscle of the perineum and levator ani, in the same direction. The finger is now introduced, and the groove of the staff felt for, immediately behind the bulb, which part is to be carefully avoided, as it is exposed by the first bold incision, for the artery of the bulb, when wounded, sometimes pours forth alarming hemorrhage. The point of the knife is introduced into the urethra guided on the back of the forefinger, and is to be moved forwards so as to reach the membranous portion, and is withdrawn by cutting any remaining resisting fibres downwards in the line of the former incisions. I then substitute a fresh scalpel with a blunt back, which is pushed on through the groove to the prostate gland obliquely upwards in a direction towards the umbilicus. The prostate is completely divided on withdrawing the knife, cutting downwards and outwards with a light pressure in the same line as the former incisions, the finger being still in the wound, regulating the action of the knife. So soon as the resistance of the prostate gland has given way before the edge of the knife, Scarpa and many other eminent surgeons recommend that great care should be taken not to carry the incisions through the coats of the bladder, which would endanger infiltration into the loose cellular tissue behind the neck of the bladder; in adults especially is this precaution requisite, as, by too free incisions at this period of the operation, the most profuse venous hemorrhage may be produced. If the stone is particularly large, safety will depend on gradual dilatation of the neck of the bladder as the stone advances in the blades, and an additional cut of any resisting muscular fibres, should that appear to be requisite. Some surgeons recommend dilatation with the blunt gorget, but I have never had occasion to employ it. The extent to which this dilatation of the neck of the bladder may be accomplished is very considerable, and, if the external incisions have been bold and dependent, stones of considerable magnitude can be extracted by caution and patience, which on such occasions are the greatest indications of skill.

Introduction of the Forceps.—The finger is now pushed on through the opening in the bladder, and the stone generally felt: the staff is now withdrawn. As soon as the stone is felt by the forefinger of the left hand, the closed forceps is introduced, which should be long, and guided by the finger. On being insinuated into the bladder, and the finger withdrawn, the handles are raised; one blade is passed under the stone, and the other above, and the instrument closed. The finger is again introduced to ascertain whether the stone is grasped in its smallest diameter, and to know that the coats of the bladder are not caught by the forceps; and, if the stone is not in its proper diameter, it may be shifted, by relaxing the hold of the forceps for that purpose. The operation is completed, by giving the forceps a quarter turn, so as to cause the short diameter of the stone to correspond with the short diameter of the wound, and *vice versa*. The stone must be drawn towards the lower angle of the wound, pressing the forceps at the same time downwards with the left hand, if that should seem necessary, so as to obviate resistance from the bones in the anterior part of the pelvis. A lateral undulating motion should be given, using at the same time no violence. The parts will be found gradually to dilate, and yield to the exit of the stone. Should the stone be particularly large, and considerable resistance be offered by any muscular fibres at the lower part of the wound, I invariably give the handles of the forceps to an assistant, whilst, with a scalpel guided on the left forefinger, I freely

divide the opposing muscular textures, and every interposing obstacle.

In cases of enlarged prostate, it is expedient that, in passing that part, the convexity of one blade of the forceps should be directed upwards, and the other downwards, where by its smooth surface it glides better over the projection, and the stone is less liable to be entangled by the tumour.

The advantage of long forceps is, that stones of considerable size can be extricated with a more powerful lever, and a more secure grasp.

Bilateral Section, and Management of the large Calculi.—Should the stone be so very large as not to be extracted except by unjustifiable violence, Dupuytren's bilateral section is to be effected; for this purpose the blunt-pointed bistoury may be introduced by the original wound, and the prostate freely divided on the opposite side, to the same extent as on the left, without any additional external incision. Thus almost any calculus, which the bones of the pelvis are capable of admitting can be removed without laceration. The dangerous consequences of such an operation may be compared to the danger of difficult parturition, where the assistance of the obstetric is required with the forceps; being lessened by dexterity, gentleness and skill, and increased greatly by violence and laceration.

Treatment of the Fragments.—Where stones are friable, the detritus and small fragments easily find their exit with the urine, through the free wound which has been made; but it will be as well to use the scoop, and to inject warm water by means of Reed's syringe. The scoop is also useful for removing small calculi, using it as a lever, the lower part of the stone being held by the forefinger to facilitate the passage of the stone.

Before removing the patient, the finger should be introduced to ascertain that there are no remaining stones. In adults an instrument called a searcher may be of use, which is a straight bulbous staff.

Method of crushing the Stone when large.—I have never had occasion to break the stone, for the purpose of facilitating its extraction, but such a necessity may occur from its great size. It is expedient, therefore, to be prepared with a suitable instrument for that purpose. It should consist of strong forceps of considerable length, with sharp wedge-shaped teeth. The handles should be strong, and fixed by a screw and nut, by the approximation of which the stone, when included within the blades, is crushed.

After-treatment.—The bandages are immediately removed. The wound washed with warm water, and all coagula detached, oiled lint may be introduced. The patient is to be placed on a bed, previously brought close at hand for that purpose, so that, with the smallest degree possible of disturbance, he may be shifted from the operating-table to it; his shoulders should be well raised, the knees elevated by a bolster, and kept slightly apart.

Dilating drinks are to be copiously administered; half a drachm of bicarbonate of soda may be dissolved in a quart bottle of barley-water, from which the patient should partake whenever inclined. The more freely the urine flows, the better. Great tranquillity should be enjoyed, and none but light farinaceous food allowed. Some patients require to be supported, who have been much exhausted by disease and irritation.

A dose of castor oil may be administered on the second day.

A large elastic gum tube is recommended by many excellent surgeons to be kept in the wound, but I have never adopted such a measure, though in cases of a very large calculus, the extraction of which has been attended with any degree of tearing of the parts beyond the boundaries of the prostate, this may be useful.

In cases of inflammation of the mucous surface, either following the operation or previously existing, attended with deposition of the phosphate of lime, the administration of opium, mineral or vegetable acids, and a decoction of the "Pareira Brava" will be indicated; and, if

the edges of the wound is encrusted with this white deposit, stimulating applications are useful, for which purpose a lotion of the decoction of bark and tincture of myrrh may be employed. The nitric acid or nitrate of silver, in solution, may be employed, with a view to promote the separation of the deposit, and the production of healthy granulation.

Observations.—There appears to me to be an important advantage resulting from the employment of the straight staff, which is that of lowering the prostate gland and the neck of the bladder towards the perineum, when its handle is only slightly inclined towards the operator, and consequently he has not to cut so deep as when the curved staff is employed, the gland being distinctly seen on completing the incision.

I confess my predilection for the lateral operation on the above principle, as applicable for almost the largest sized stones which are likely to occur in the practice of most surgeons, in preference to any other measures which have been advocated. The opening can be enlarged to a great extent in the same direction; indeed the bolder and freer the incisions on all occasions, the better; and with the "bilateral section" we have an additional resource; and beyond this, for stones of the very largest dimensions, we have the choice of the recto-vesical operation, in which the incision of the perineum is made to extend through the tunics of the rectum and sphincter ani muscle. There is less danger to the patient in these instances from division of the neck of the bladder beyond the boundaries of the prostate, owing to the frequency of the incisions, and consequently the dependent opening obviating infiltration of urine. There are some extraordinary instances in which the "high operation" above the pubes may be expedient; but it can only be then justifiable where the patient is very thin, and the stone so enormous as to be inextricable by any other measure.

The result of the above principles is the best proof of their correctness, and is therefore annexed in the notes, wherein the average number of the fatal cases is one in fifteen. My last seventy cases have all been successful.

The wound must be left entirely open, and permitted to granulate from the bottom. All attempts to promote union would only endanger infiltration of urine into the cellular tissue. A small piece of oiled lint may be introduced into the wound to facilitate the current of urine; but I usually adopt nothing of the kind.

The urine generally commences to flow by the natural passage on the eighth day, sometimes in children on the fourth or fifth. In adults it may not occur till the fifteenth or twentieth day.

Encysted Calculi.—The only instances which I have met with were two: one in which a small appendix or neck was lodged in the anterior pubic portion of the bladder, where the portion broke off and ulcerated its way out, on the fourth day (see fig. 7), and one in which it was necessary to perform what is termed, "l'opération à deux temps" (Nos. 49 and 69). Both recovered. I would strongly

reprobate all forcible attempts to remove these encysted calculi, when we are so unfortunate as to meet with them.

Case.—James Diggs, aged four, a remarkably fine European child, of very fair complexion. His parents brought him to me from Delhi to Meerut, when he was only three years old; but, apprehending convulsions by so serious an operation, from the highly nervous irritability in a child of that tender age, I advised them to defer the operation, which they did till the following cold season, when they brought him to me at Calcutta. The pain attacked him in paroxysms of intense agony which would last two or three days, during which his mother feared convulsions. Intervals of complete absence of pain would occur for a fortnight. Though a remarkably plethoric child, these attacks would, in the course

of forty-eight hours, reduce him so considerably as greatly to alter his appearance. In the intervals, the natural resiliency and strength of his constitution almost as rapidly restored him to flesh and high colour. The alternate states of acute suffering and complete ease continued for two years. Nothing further was remarkable; all the ordinary symptoms of stone were manifest in a high degree.

The operation was attended with no difficulty or delay. The stone was seized lying towards the pubic region, and with a slight resistance yielded with a snap as though some slender point had been broken off. Introducing my finger, and directing it towards the situation from whence the stone was extracted, the pubic region, I distinctly felt a point of calculus sticking in the coats of the bladder. I immediately stated to the professional men present my conviction that a neck or peduncle was encysted, being enveloped in the mucous coat, and become insinuated between the muscular fibres of the bladder, forming a cyst. I requested Dr. Lightfoot to satisfy himself on the point, which he did. I then observed that we must suspend all further interference for the present; to attempt to extricate the encysted portion would be fraught with danger; "l'opération à deux temps" might be requisite, but that I should be disposed rather to leave the result more to the effects of nature, anticipating that the remaining portion might not improbably be extricated, by the natural process of ulceration, and drop into the cavity of the bladder.

The child was immediately removed from the table. The operation, and consultation on the case, had occupied about four minutes. The circumstances were fully explained to the friends by the professional gentlemen present.

The result fully corroborated our expectations in this interesting case. The encysted portion dropped on the bed on the third day, having been carried out by a jet of urine through the wound.

The child recovered without any unfavourable symptom, and on the eighth day I found him playing on the verandah with his brother. A few days afterwards he was able to return to Delhi, from whence his mother wrote to inform me of his arrival; adding that "he was in the most perfect and robust health." I have recently seen the child, in passing through Delhi; he was in excellent health. It is now some years since he was operated upon.

The expediency of avoiding any attempts to complete the operation in all cases of accidental difficulty is, I imagine, fully established, and I think illustrated in the above case. There is no harm in waiting, but much hazard in attempts to overcome the difficulty. There is no operation in surgery in which more unforeseen, and consequently unavoidable, difficulties may sometimes arise than in lithotomy.

The case was a fortunate one, for the mucous coat of the bladder was decidedly injured; I felt the edges jagged at the point of fracture; cystitis was therefore more likely to have occurred, which Baron Boyer states, "est la cause de la mort des trois quarts des malades, qui succombent à la suite de l'opération de la taille." Surgeons, however, in the present day refer the death in most cases after lithotomy to inflammation set up in the deep-seated cellular tissue round the neck of the bladder and rectum, between the levator ani and deep perineal fascia, and communicating with the peritoneum.

Figure 4 represents the form and dimensions of the calculus.

"l'opération à deux temps," as it has been called, can only be undertaken where the stone is found to be partially encysted, and where it cannot be removed at the time without violence. The only occasion on which this mode of procedure occurred to me was the following, where indeed it became a matter of necessity.

Case.—Jhoonloo, Moosulman child, aged seven years, in a delicate and irritable state, brought on by unusually severe suffering from the stone for about two years: whereby he had

been so greatly reduced that his parents for the last ten days had despaired of his life, as he had become quite helpless: they came to me for relief in November, 1834. The operation was undertaken as a last alternative, and at the earnest solicitation of his father. The straight staff and scalpel were the only instruments employed, and there was no difficulty until the introduction of the forceps. The lower end of the stone was repeatedly seized, and as often escaped from the grasp of the forceps, being evidently retained, either by the firm contraction of the bladder, or by a portion of it being encysted. Finding all prudential efforts unavailing, and the child becoming much exhausted, I desisted; administered a full dose of tincture of opium combined with aromatic spirit of ammonia, and sent him to bed. Constant fomentations were applied. These measures had the most happy effect. The child rallied, the anodyne and soothing treatment was persevered in, and on the ensuing morning the stone was removed in the following manner. An assistant, seated on a chair, placed the patient on his lap with his back towards him, bent and raised the knees by introducing his arms under his ham, the perineum being lowered as much as possible, and the body kept in the erect position, so that the stone might gravitate as much as possible towards the lower part of the wound. Introducing my finger, I felt the calculus, which was immediately seized by the forceps and withdrawn. One extremity of the stone had been lodged in a "cul de sac" of the bladder, as was evident by the form of the calculus, that extremity being of smaller diameter than the other, and having a clearly defined neck, and rough extremity where it had been compressed, apparently by the separated fibres of the muscular coat of the bladder; which satisfactorily accounts for the impediment. I have not the slightest doubt that, had I persisted in my efforts to remove the stone, the child would have expired on the table; and the expediency of procrastination on the occasion is thus exemplified. Difficulties in lithotomy do sometimes occur when least anticipated, requiring all our self-possession and deliberate reflection. There is a natural reluctance in the surgeon, on whom the credit and responsibility of the operation depend, to allow it to remain incomplete, and hence, the moment of hesitation once having passed, some of our most celebrated surgeons occasionally, and young surgeons frequently, have involved themselves and patient in the most lamentable consequences.

Arterial Hemorrhage.—Three instances of alarming hemorrhage have occurred to myself, one of which proved fatal. Pressure should be immediately applied with the finger on the internal pudic artery, against the ramus of the ischium, and if possible the vessel should be secured. This will be more practicable in a thin subject. Should that be impracticable, a large gum-elastic tube should be introduced through the wound to the bladder. Several slips of lint are to be passed along it to a sufficient depth, and retained, if requisite, by compress and bandage. Carefully avoiding the bulb of the urethra, never cutting beyond the prostate, and keeping as far as possible from the ascending ramus of the ischium, are the great preventives of hemorrhage.

In No. 23, the patient was deluged with blood. Immediately after completing the incisions, the stone was extracted, which when accomplished, the hemorrhage had ceased. The wound was plugged, and the internal pudic artery compressed with the finger for a long time; but, on removing the finger, the hemorrhage returned—syncope, and alarming symptoms came on. The patient sank during the night. There was apparently an irregular distribution of the internal pudic. *Post-mortem* dissection was not permitted.

No. 71 was another severe hemorrhage, from a large branch given off close to the internal pudic. So near was it to the artery that Mr. Evans, who assisted me, thought it was that

vessel. We seized it immediately with Weiss's spring ligature forceps, and secured the vessel. The other portion of the artery retracted and did not require ligature. This patient did extremely well.

A third, and similar case, occurred to a sirdar named Runjeet Sing, at Lahore (No. 91), and which also did well, on securing the bleeding vessel.

Venous hemorrhage was very profuse in an old man who was operated on at Meerut, assisted by Dr. Bell, 11th Dragoons, and Drs. Sievright and Pine of the Cameronians. Alarming syncope and convulsions were the consequence. The latter, perhaps, from the shock of the operation. The blood was evidently venous. This patient, however, recovered.

Fatal Case in an old Subject.—The patient (No. 3) may be said to have been seventy in constitution, though he stated his age as thirty-seven, for he had the appearance of an old man; this is fully accounted for by his having laboured under the disease thirty years. He never properly rallied from the first, though he lingered for a month. In short he died, as many old patients do, without reaction.

Curiously-formed Calculus.—There was an instance in which the calculus had a long appendix projecting a considerable distance into the membranous portion of the urethra, having on its upper surface a smooth groove along which the stream of urine had flowed. The sufferings of this patient were very acute.

Tetanus.—Two of my patients fell victims to this dreadful disease: they occurred about the same time, during the unhealthy season of May, when the hot winds had subsided and easterly winds prevailed. The rains had not set in; the heat at that time was suffocatingly great. This particular period is unfavourable for operating. They occurred in the early part of my career, and may prove a valuable suggestion to my younger professional brethren to avoid this season. Another child also laboured under tetanus, yet recovered. The administration of hemp now promises to be a valuable remedy in this disease.

Peritonitis.—This formidable disease is liable to occur, especially in children. One or two of the cases have happily recovered among my patients.

(To be continued.)

THE CAUSES OF SUDDEN DEATH.

By MALCOLM HILLES, Esq.

(Continued from p. 58.)

What a deep but painful interest has been added to the part of our subject at present under consideration, namely, the *modus operandi* of carbonic acid gas on the human subject especially, and animal life generally, by the recent coal-pit explosion at Barnsley, by which seventy-three fellow-creatures have been in an instant deprived of health and life, and their wives and families left unprotected.

I little expected, when I first entered upon the discussion of this matter, that such a melancholy opportunity should be afforded me of illustrating its effects, and of on enquiring to arouse public attention to the occurrence of these periodical explosions, one of which is far more extensively fatal than all the railway accidents that occur annually in the United Kingdom, and yet are passed over in comparative silence.

The coal-mines of this country, more especially those of the north-eastern district, afford, unhappily, numerous instances of sudden death being caused by the agency of carbonic acid gas.

It is generally supposed that, in the dreadful explosions of fire-damp which occur so frequently, the destruction of life is caused by the explosion itself, and that many of the individuals are burned to death. This is not the case: most of the deaths which occur in such unhappy accidents are produced by the inhalation, by the workmen, of the carbonic acid, which is formed at the period of, or immediately after, the explosion.

The *fire-damp*, as it is usually termed by the workmen, consists chiefly of carburetted hydrogen gas. On the explosion of this gas, the carbon unites with the oxygen of the atmospheric air, and thus carbonic acid is formed; this fills the pit or mine, and, being inhaled by the workmen who have escaped the immediate effects of the explosion, produces a rapidly fatal result.

In corroboration of these assertions, Dr. Fife, in his evidence before the Parliamentary Committee on Accidents in Mines (a) states, that the persons he examined had died from suffocation occasioned by the "choke-damp," or carbonic acid gas. Other witnesses depose to the same fact; indeed the appearance of the bodies, few of which present any trace of injury, places the matter beyond doubt.

NOTE.—Having paid a good deal of attention to this subject, after the explosion which took place in the Jarrow colliery, a few years since, when upwards of one hundred lives were lost, and having had a somewhat lengthened correspondence on the matter with the Coal-trade Committee of the north, then sitting in Newcastle, I trust I may be excused for entering more largely into the question than I otherwise should, especially when it is recollected that seventy human beings have been hurried into eternity, without a moment's warning, by the concurrence of circumstances which, it is my opinion, might have been prevented without any very serious outlay on the part of the proprietors of the mine, and which should be prevented in all similar instances.

It will be sufficient for our purpose at present to state that, in the working of all coal mines, especially those where bituminous coal abounds, a large quantity of carburetted hydrogen gas is constantly being given out from the beds, or broken masses of coal. This gas, in its pure state, is simply inflammable, and burns freely, but, when mixed with a certain proportion of atmospheric air, forms a compound which explodes on being exposed to the light of a candle, lamp, or other similar agent.

When mixed with a larger quantity of atmospheric air, the gas loses both the equalities, and becomes comparatively innocuous.

In the ventilation of coal-mines the object is, therefore, to introduce a sufficient quantity of atmospheric air into the mines, so as to mingle with the carburetted hydrogen gas in the proportion necessary to destroy its explosive nature, and at the same time to remove it, thus diluted, from the mine, and to supply its place with pure atmospheric air for the support of the workmen and horses engaged in the removal of the coal.

This object is attempted to be attained by the establishment of a strong draught of air through the various parts of the mine, which descends by an open shaft toward the *downcast shaft*, and ascends by a similar open shaft, namely, the *upcast shaft*.

In some instances there is but a single shaft, which is divided into two by a partition or *brattice*, by which means the descending and ascending currents of air are maintained.

In order to establish the current of air, a fire is usually lighted in some part of the upcast shaft, which causes the expansion of the air in this part, and consequently the rapid ascent from the mine of all air contained therein.

The current of air thus established is in some cases so strong as to blow out the candles and otherwise inconvenience the workmen. For the purpose of ventilating all parts of the mine, this is divided by partitions of various kinds, provided with doors and other contrivances, by the opening or closing of which the current of air may be changed in its course.

This mode, however, effects only an incomplete ventilation of the mine, as the air cannot be directed sufficiently into the recesses of the mine, nor to any part which does not lie between the two shafts as already described.

(a) See Report, Session 1835. Questions 1430 to 1442.

As many of these recesses are newly formed by the men in the working of the coal, it results that the parts of the mine occupied by the workmen are frequently the least ventilated. Hence, indeed, the apparently anomalous cases of explosions occurring in what are considered the best ventilated mines.

Another situation where the carburetted hydrogen gas collects is in the *waste*, which is the extreme part of the mine, where the coal has been worked out, and the roof is allowed to fall.

It follows, therefore, that the use of an open light in these situations—and occasionally, it is supposed, even of a Davy lamp—causes an instantaneous explosion.

The strong current of air, already stated as being established in the mine, contributes to an accumulation of the carburetted hydrogen gas, or fire-damp, in these places; as the motion of this fluid, and its density caused by the rapidity of its motion, confine the gas to the recesses, and prevents that admixture so necessary to destroy its combustibility, establishing, in some cases, that insufficient mixture only which renders the gas explosive. In these cases the introduction of an open light is alone wanting to produce the unhappy result—a want that is too often supplied by the rashness, or ignorance, or neglect, of some one of the workmen or boys in the mine.

That the air and gases generated in the mine, and brought into contact under these circumstances, will not unite, is sufficiently known. Indeed, the workmen themselves are aware of this fact, and adopt several contrivances to remedy the evil by forcing the gases into more immediate contact.

Let us say, then, that an explosion takes place; the effects are almost instantaneously produced; from the expansion of the gas at the moment of explosion, many of the articles contained in the mine or shafts are driven upwards into the air, to the height of some hundred feet, parts of the mine, or its works, are destroyed, and some lives sacrificed. But, the explosion having ceased, there results, as in all cases of combustion, the formation of carbonic acid gas, which fills a large portion of the mine, the remainder being filled by water, and the atmospheric air which rushes in to supply the place of the carburetted hydrogen gas previously destroyed.

It is now that the great work of destruction begins: all living beings—men, boys, and horses—fall victims to the gas, which, entering the lungs at the moment of inspiration, produces its usual deadly effects; some of the former endeavour to prevent this by pressing their caps, jackets, &c., against their mouths, or by throwing themselves on the ground. Vain efforts! they must breathe: to breathe is to die—they breathe and perish!

Most of the bodies are found without any marks of injury, evidently proving the cause of their death to be the inhalation of the carbonic acid gas.

A few years since, I submitted a plan of effectually ventilating coal-mines to the Coal-trade Committee, but was not so fortunate as to induce them to adopt it. The plan is, by the use of iron, copper, zinc, or brass tubes, to convey the carburetted hydrogen gas from all parts of the mine, through the upcast shaft, into the air. These tubes could be so arranged as that a smaller or short tube might be attached to them, and conveyed to the farthest recess of the mine, so as to carry off the gas from the mine as it escapes from the coal.

The details of, and other circumstances connected with, this plan would be out of place here. I trust, however, that an opportunity may be embraced of putting it to the test of a trial, at no distant period.

Few of the persons in the mine at the time of the accident escape, as it is extremely difficult and dangerous to attempt their relief before the carbonic acid has been withdrawn from the pit. Many have perished in the humane effort to rescue their fellow-workmen.

It is much to be regretted that public atten-

tion has not been more effectually awakened to this subject; the voices and efforts of a few individuals are impotent. When we reflect on the rapid strides that *Anna* now making, in conjunction with her sister, *Science*, surely it is not too much to hope that *Science* might shed a ray of light on this question, and assist in preserving so many valuable lives to their country, their wives, and their families.

Carbonic acid is not the only gas which is rapidly destructive of animal life. All the *irritants* (a) gases, namely, nitric oxide, nitrous acid vapour, muriatic acid, chlorine, ammonia, sulphurous acid, and some others less important, are poisonous.

These act destructively by causing a spasm of the glottis, and, in my opinion, of the muscular fibres of the air-cells of the lungs, so as to exclude the atmospheric air, and by inducing an inflamed state of the mucous membrane lining the air-tubes.

It is seldom, however, that sudden death is produced by any of these gases, as the irritation produced by their inhalation precludes the possibility of their being taken in when highly concentrated, or in large quantities. None are so immediately fatal as the carbonic acid gas.

Of the *narrotic* gases the most fatal are the carbonic acid already spoken of, and the sulphuretted hydrogen. Carburetted hydrogen, so extensively found in coal-mines, and so much used for the purposes of lighting, though less suddenly fatal than either of these, is extremely injurious to animal life (b). An experiment on the inhaling of this gas had nearly proved fatal to *Sr Humphry Davy*.

Sulphuretted hydrogen gas, in a concentrated state, is equally fatal as carbonic acid. As this gas is naturally produced by the decomposition of animal and vegetable substances, and is especially disengaged from common sewers and receptacles of excrementitious matter—and therefore abounds in our metropolis and all large cities—the effects produced by it cannot be too generally known, particularly as our authorities have of late adopted the peculiar method of ventilating the sewers of London at the expense of the streets and dwellings of the inhabitants, and have thus converted the thoroughfares into so many overground sewers for carrying off the noxious gases from the underground sewers (c) a species of reciprocal advantage, which, however beneficial in other respects, can be of but little service to the inhabitants.

The following extract (d) is most instructive on this head:—"The gases formed in the 'fosses d'aisance' of Paris consist chiefly of combinations of ammonia, sulphuretted hydrogen, and nitrogen. These exhalations produce the most fatal effect. Often the individual exposed to them perishes in a moment: his head and arms falling, and the trunk being doubled up, from the instant loss of muscular power. If death does not immediately occur, the victim, when he recovers from the first effects of this exposure, is affected with pains in the head, nausea, fainting fits, severe pains in the stomach and limbs, constriction of the throat; sometimes he utters involuntary cries, or lapses into delirium, accompanied with the sardonic laugh and convulsions; or tetanus ensues."

Mr. Hallé (e) has given an interesting narrative of an attempt made to empty one of these pits, in presence of the Duc de Rochefoucault, the Abbé Tessier, himself, and other members of the Academy of Sciences, who were appointed by the French Government to examine into the merits of a pretended discovery for destroying the noxious vapours.

The pit chosen was ten feet and a half long,

six wide, and at least seven deep; and repeated attempts had been previously made, without success, to empty it. For some time the process went on prosperously, when, at last, one of the workmen dropped his bucket into the pit. A ladder being procured, he immediately proceeded to descend, and would not wait to be tied with ropes. But hardly had he descended a few steps of the ladder, when he tumbled down without a cry, and was overwhelmed in the ordure below, without making the slightest effort to save himself. It was at first thought he had slipped his foot, and another workman promptly offered to descend for him. This man was secured with ropes in case of accident. But scarcely had he descended far enough to have his whole person in the pit, except his head, when he uttered a suppressed cry, made a violent effort with his chest, slipped from the ladder, and ceased to move or breathe. His head hung down on his breast, the pulse was gone, and this complete state of asphyxia was the affair of a moment. Another workman descended with the same precautions, fainted away in like manner, but was so promptly withdrawn that the asphyxia was not complete, and he soon revived. (a)

It was found impossible to go on with the operation of clearing out, and the pit was shut up again. The first workman never showed any signs of life; the second recovered after discharging much bloody froth; all the persons in the vault were more or less affected; and a gentleman who, in trying to resuscitate the dead workman, incautiously breathed the exhalations from his mouth, was immediately and violently seized with the convulsive form of the affection.

INHALATION OF ETHER DURING LABOUR.

By EDWARD LATHAM, Esq.,
Royal General Dispensary, Aldersgate-street.

Since the valuable remarks of Dr. Simpson, of Edinburgh, as to the propriety and safety of administering ether by inhalation during parturition, I have had an opportunity of testing its effects in a case under my own care; when Dr. Lloyd, Physician to the Royal General Dispensary, Aldersgate-street, was kind enough to superintend and observe the effects of the agent. Mrs. —, aged thirty, and the mother of two children, having read the public reports of childbirth without pain, expressed to me a strong desire to have the ether administered, and so to rid herself of that amount of suffering which she well knew it was her lot to undergo. She had been in labour about three hours; the os uteri was nearly fully dilated, and all the soft parts yielding. The membranes, with the liquor amnii, formed a large bag, which occupied the cavity of the pelvis; and, during the absence of pain, the child's head was felt above the brim, in which position it remained for half an hour, notwithstanding that the uterine efforts recurred regularly, and with moderate energy, once in about every five minutes. When the tip of the index-finger was applied to the head, it could be tilted upward considerably; and, as the presenting bag of membranes was large, it was supposed that an unusual quantity of liquor amnii existed, and retarded labour. Dr. Lloyd now commenced the administration of ether by means of Smee's hot-water inhaler; and in about four or five minutes our patient manifested the usual symptoms of unconsciousness—the pulse falling, and the pupils becoming dilated, &c. &c. The apparatus was now removed for some minutes. The uterine contractions continued regularly, though, we thought, somewhat abated in force. I now ruptured the membranes, when an immense gush of liquor amnii took place, and

(a) A somewhat similar occurrence took place a few years since in one of the pestilential beds, named churchyards, in London. This has been detailed and frequently brought before the public by that indefatigable philanthropist, Mr. Alfred Walker.

the child's head gradually descended into the pelvis. Consciousness having returned, the patient said that she had felt no pain, but had been in a comfortable sleep, and dreamt that her child was born. She now began to feel the pains recur with their usual severity, and earnestly entreated us to give her the ether again; she even seized the instrument from Dr. Lloyd's hands and applied it to her mouth herself. After three minutes' inhalation, unconsciousness was again established, and, though the inhaler was occasionally removed, she was kept under the lethean influence for about twenty minutes; after which time the apparatus was not again applied. The child gradually descended, the head pressing upon the perineum, which became perfectly relaxed, and the head and shoulders were expelled by one strong, continuous uterine effort, in eight minutes from the withdrawal of the inhalation. During the pains I applied my hand frequently to the abdomen, and found that the muscles were much more lax during than previously to the administration of ether. A few minutes after the expulsion of the fetus a considerable gush of blood came from the uterus, which was now felt to be large and relaxed, but soon contracted again under the firm and steady pressure of the hands; the placenta quickly followed, and a broad bandage was tightly applied. (It must, however, be stated that our patient had suffered considerable hemorrhage after the expulsion of the fetus in her previous labour.) On questioning her subsequently, she stated that she had felt no pain with the exception of the last, and that she would strongly recommend any one to take the ether under similar circumstances, expressing her gratitude to us for having applied it. No inconveniences have since followed, and the patient is convalescing as favourably as possible. It is of course impossible, from an isolated case, to draw any just conclusions as to the admissibility of this agent in parturition. This case, however, so far as it goes, is satisfactory; and if we can by any means alleviate the first curse, which has for so many ages been incidental to the parturient state, we shall confer the greatest boon on those who are deserving of all our sympathies, and worthy of our best energies.

PROGRESS OF MEDICAL SCIENCE.

• France.

ACADEMY OF SCIENCES.

Meeting of March 15; M. BRONGNIART in the Chair.

Nervous Fluid.—Professor Dumas laid on the table a paper by M. Matteucci, relative to the mode of action of the nervous system. That physiologist admits the existence of a nervous fluid analogous in nature to electricity. Its origin is in the muscular textures of the body, where it arises from a chemical process, viz., the action of their free acid on the alkaline principles of the blood. The fluid thus produced would be carried along the nerves, its conductors, to the brain, whence by the influence of volition it would be conveyed to the muscular system again, there to determine contraction.

Ether.—M. Doyère read a short account of a method which he proposes, for the purpose of limiting, to a certain proportion, the amount of ethereal vapour admitted into the lungs by inhalation.

ACADEMY OF MEDICINE.

Meeting of March 17; M. BEGIN in the Chair.

PRESERVATION OF ANIMAL MATTER.

M. Ponsseville read a report on the methods of preservation recommended by MM. Gannal, Dupré, and Surquet.

With regard to the mixture of carbonic and sulphurous acids, employed by M. Dupré, the reporter stated its inability to preserve or

ganic substances beyond a very limited time. M. Gaunal's method, consisting in the injection of a solution of alum, appears to acquire, by the addition of an arsenical preparation, the property of preserving indefinitely animal substances; while the fluid adopted by M. Surquet contains no arsenic, but preserves in the most perfect manner possible—an experience of two years now demonstrating positively the fact.

M. Dubois presented a case of congenital deformity of the hand and foot. The learned professor having expressed his intention of resuming the consideration of this case on an early occasion, we shall until then postpone its history, of which we have at present obtained only an imperfect sketch.

M. Hutin, surgeon-in-chief of the Hôpital des Invalides, presented a patient, in whom, after angina, the soft palate had formed adhesions with the posterior part of the pharynx, so as to separate entirely the nasal cavity from the mouth, and to preclude any communication whatever between them. Olfaction was completely destroyed, and taste partially. M. Hutin was of opinion that the restoration of these two senses might be expected if the morbid adhesions were removed.

PARISIAN MEDICAL SOCIETY.

Meeting of March 16; Dr. SHRIMPTON in the Chair.

CARCINOMA, BY M. PIGNE.

(Continued from p. 58.)

The shooting pains, usually considered as characteristic of cancer, are connected with the degree of its hardness; they are remitting, and the shortness of the intervals of remission indicate the approach of the period of maturity. This maturity may be considered to be the death of the pathological product; softening is its first phenomenon. The occurrence of ramolissement is hastened in proportion to the activity of the power of assimilation in each individual; hence it is very speedy in childhood; less so in the adult, and still less in the aged subject. It is only when cancer softens, that the veins of viscidous parts send ramifications into the tumour—a fact proved by the possibility, at that period, of throwing injections into the carcinomatous production through the vessels of neighbouring parts. By contact with carcinomatous matter, the walls of the veins and lymphatics become weakened, *atonized*; the circulation in the venous system is difficult; and the production of anasarca, œdema, and serous effusions, much facilitated.

On the progress of cancer, even apparently slight changes of air, diet, habits, &c., exercise the most accelerating influence: hence, the custom of leaving carcinomatous patients some time in hospital before the operation is decided upon, is much to be deprecated; and the necessity for immediate removal of cancerous tumours may be said to be as great as that of immediately operating in cases of incarcerated hernia.

By the absorption of cancerous juice into the system, a twofold effect is produced—1, its deposition, in the shape of infiltration, in the organic framework of tissues; and 2, its agglomeration into tumours—a circumstance coincident with destruction of the primitive texture of the part. The distinction between these two anatomical results of absorption can readily be established, with the assistance of maceration—a process which removes the infiltration, leaving the tissue of the diseased part in its natural state.

Reproduction of carcinoma is observed in three distinct cases:—1, After the spontaneous maturity of cancer, without inflammation; 2, after the spontaneous maturity of cancer, complicated with inflammation; and 3, in consequence of traumatic injuries or of operations. In the first case, the reproduction is more particularly confined to organs similar to that which was the original seat of the disease, and the secondary tumours are usually of the same nature as those to which they have succeeded. In the second case, it is in secretory organs, and especially in the

lung, that reproduction is observed. The secondary tumours here vary from the primary, and their progress is unusually rapid. In the third instance, reproduction takes place generally in the liver, and usually by infiltration.

The following cases illustrate the great rapidity of development of cancer in the circumstances alluded to. In the year 1840, a man, aged thirty-two, was admitted into Professor Bérard's wards at the Hôpital St. Antoine. The patient had been struck with violence in the epigastric region by the shaft of a cart, and, notwithstanding a very attentive exploration of the abdomen, no tumour whatever was detected in the injured spot before the third day, when a swelling of the size of an egg was first noticed. Death took place on the ninth day after the accident, and an encephaloid tumour of the omentum, equal in size to the head of a full-grown fœtus, was discovered on dissection.—A woman affected with cancer of the breast became pregnant. The cancerous affection progressed, and abortion took place at the fifth month; a tumour, four inches in diameter, was found on the fetal aspect of the placenta which was cancerous.—Secondary tumours progress faster than primary cancers; the latter are usually solitary, the former never. Hence the precept, never to operate upon a secondary carcinoma.

Dr. Montgomery read a paper on "Injured Arteries," and, taking Mr. Seton's case as a text, defended the practice adopted by Mr. Liston in that well-known instance.

An interesting case of a medico-legal nature, in which the liberty of a British practitioner at Nice, appears to have been trifled with, was then laid before the society. We will on a future occasion communicate the case, with the full details which it deserves.

FACULTY OF MEDICINE.

LECTURES ON GENERAL PATHOLOGY, BY PROFESSOR ANDRAL.

It is not a little remarkable that in the "Hippocratic Collection" no attempt at a classification of diseases is to be found. Themiso's division does not deserve that name. Galen divides all maladies into two great classes: in the first, he places those which he attributes to an alteration of one of the elements, such as heat, dryness, moisture, &c.; in the second, those diseases referrible to the alteration of the same combined elements, and the diseases of dissimilar parts or organs. This second class contains four genera—1, vices of form; 2, of number; 3, of volume; and 4, of structure. Together with Galen's theoretical views, this classification for fifteen centuries governed medical science. It was only towards the sixteenth or seventeenth century that other classifications were instituted: the nature, the seat, and the causes of maladies being conjointly or separately taken for the basis of the superstructure.

The first idea of modern classifications is due to Felix Plater; in 1731 Sauvages published the first edition of his "Nosology," which he perfected only in 1763. Sauvage established ten classes of maladies, and, in each, numerous genera and species. The following is his division:—1, vitia; 2, febres; 3, phlegmasiæ; 4, spasmi; 5, anhelationes; 6, debilitates; 7, dolores; 8, vesaniæ; 9, fluxus; 10, cachexiæ. These ten classes contain 44 orders, 315 genera, and 2400 species.

Linnaeus also attempted a classification of diseases, in which he was not so successful as in his division of plants. It is now, as it deserves, forgotten, and we will not drag it from merited oblivion.

Cullen establishes four classes:—pyrexia, neuroses, cachexia, and locales. In the first class he places phlegmasia and hemorrhagia; in the second, an order called "adynamia;" and in the fourth a large number of diseases which are totally unconnected with each other.

Vogel has five classes:—1, pyrexia; 2, phlegmasia; 3, hemorrhagia; 4, neuroses, 5, organic.

Nufeland, four classes:—1, febres; 2, in-

flammationes; 3, exanthemata; 4, imbibitiones.

P. Franck, seven classes:—1, febres; 2, inflammationes; 3, exanthemata; 4, imbibitiones; 5, profusiva; 6, retentiones; 7, neuroses.

Sprengel, seven classes:—1, febres; 2, inflammationes; 3, exanthemata; 4, morbi excretorii; 5, neuroses; 6, dolores; 7, cachexiæ.

Hildenbrand forms five classes:—1, febres; 2, cachexiæ; 3, neuroses; 4, ecchyas (fluxus); 5, locales.

Selle founded his classification upon a different basis; his object was to divide maladies, according to their presumed nature, in such a manner that to each class should correspond a peculiar method of treatment. Thus he separates into distinct classes—inflammatory, bilious, and putrid affections, in each of which, for instance, a variety of fever, pneumonia, pleuritis, &c., may be found. He thus forms eighteen classes, which it would be tedious to enumerate.

Such were the principal classifications which had been introduced into science previously to Pinel. He endeavoured to simplify the nosological tables, and created five classes of maladies, the first of which is entirely attributed to fevers, and is subdivided into the following six orders:—1, inflammatory or angiotonic fever; 2, bilious or gastric fever; 3, mucous fever, or P. adénoménigée; 4, putrid or adynamic fever; 5, malignant or ataxic fever; 6, the plague, or "fièvre adéno-nerveuse." Now, these are forms really observable at the bedside of the patient, but they do not constitute separate diseases; indeed, in the progress of one case of fever, several of these forms will be assumed successively by the malady; it is in typhoid fever that they are most distinct. But it is not only so in this disease: and it becomes an interesting fact that the vivid picture which Pinel draws of adynamic fever was, in all probability, portrayed from the cases of pneumonia so frequent in the aged; and which Pinel had ample opportunity to study in his hospital wards at Bicêtre. The symptoms of general infection produced by phlebitis also resemble closely those of adynamic fever; Pinel's division, although expressive of differences existing in nature, cannot therefore, nowadays, be entertained: let us add, that, in this class of febres, Pinel did not place eruptive fevers, but forced them into the class of phlegmasia, by which his second great division is constituted. In a third class he placed hemorrhages; and the fourth class contains neuroses, and is perfectly instituted; this class is subdivided into five orders—1, neurosis of the senses; 2, of intellect; 3, of locomotion and voice; 4, of nutrition; 5, of the genital functions. Pinel's fifth class is consecrated to organic diseases, and contains a singular assemblage of ill-assorted maladies—syphilis, gangrene, cancer, scurvy, and intestinal worms, for instance.

After Pinel, Broussais appeared, and struck out fevers from all nosological classifications. With his great powers of induction, and his remarkable talents for observation, he endeavoured to prove that fevers were always symptomatic of phlegmasia: he succeeded in demonstrating that in a great number of cases in which dyspnoea, for instance, was considered as a malady, it deserves, in reality, only the name of "symptom"; his attention was chiefly fixed upon diseases of the solid textures; but, in scurvy, for instance, he did not refuse to acknowledge the alteration of the fluids of the body. His principal glory is to have established the great principle of the coincidence of organic with functional change; to have increased the number of those secondary phenomena which we call symptoms, and diminished the number of those primary lesions to which alone the name of disease is due; also to have shown that, in many instances, it is not the weakness but the over-excitement of an organ which interferes with the regular accomplishment of its functions.

Irritation constituted for Broussais the pathological element of a great class of diseases, into which he introduced three orders, according as

It might be referred to inflammation, to secretion, or to nutrition. In this class are placed many maladies which do not really depend upon irritation, and it cannot, therefore, be considered as being in harmony with the present state of science. Pyrexia and alterations of the blood deserve a special place in nosological classifications; and we must consequently set aside, at present, Broussais's divisions: we have proposed one which we consider to be complete, and which we are ready to defend.

During its progress each malady is revealed by certain special phenomena called "symptoms," and which intellectual labour teaches us to convert into "signs" indicative of its seat and nature. Were we not limited in our time, we would now begin the study of symptomatology, or semeiology; but the few days which are left oblige us to relinquish this plan, and to postpone these important subjects to the next winter session. We will at present merely follow disease, in its successive periods—or in its evolutions.

When health ceases to be perfect, a moment comes when the phenomena observed cannot serve to characterize any special malady, and still indicate a departure from health. These are called prodromata. The prodromic period of a malady cannot, in sound logic, be separated from that of the disease itself—it is in reality the disease, before it has assumed a determined form or a precise seat. In some affections the premonitory signs are very distinct from the disease itself; this is observable in acute phlegmasia; in typhoid fever the contrary is the case. They are more frequent in acute than in chronic disorders. In violent and acute phlegmasia, the prodromic period may be absent; but pyrexia, inflammations of the mucous membranes, or of the skin, are most generally ushered in by premonitory signs. The duration and intensity of prodromata vary considerably; in great epidemics, it is not uncommon to observe the premonitory signs of the prevailing disease, while the symptoms of the latter fail to manifest themselves.

Promonitory signs may be divided into two very distinct classes: one set, and it is the most frequently observed, present no special characters by which the impending disease can be foretold; the other, on the contrary, is of great assistance in the diagnosis of the symptoms which will follow. The prodromata of the first class may be studied in the functions of nutrition, or of the organs of relation. Thus the intellectual powers are not infrequently impaired, and muscular exertions become more difficult. A sense of lassitude is complained of, and fixed or errant pains are observed in the joints. Headache, vertigo, giddiness, disturbance of vision or of olfaction, may be noticed; the expression of the countenance is often singularly modified: flushing of the face, injection of the conjunctive, or paleness, are so striking that even unprofessional persons can recognise the imminence of disease: "Physiognomia in altera, ut et profani, morbum instantem designant." (Hildenbrand.) Sleep is interrupted and disturbed. With regard to the nutritive functions, the appetite is lost; the tongue is coated; constipation or slight diarrhoea appears; the skin is dry, the urine changed in its aspect; an habitual evacuation, epistaxis, or hemorrhoidal flux, is suspended; the secretion of an issue or blister diminishes in abundance. Each of these phenomena is doubtless trifling in itself, but, when considered in conjunction with the disease, they acquire considerable pathogenic importance. It sometimes happens that the days which precede the appearance of disease are marked by unusual mental activity and digestive power—a rare occurrence, but one which deserves notice.

Hemorrhages may not be ushered in by any symptoms whatever; but when these symptoms do exist, they are always the same, and constantly indicate congestion. Galen states that he obtained considerable credit in Rome, from the circumstance of his having on various occasions foretold epistaxis, in consequence of the pre-

sence of particular symptoms. Hemoptysis may not be preceded by any premonitory signs, but in many cases it is announced by dyspnoea, palpitations of the heart, heat of the interior of the thorax, &c. The hemorrhoidal flux may be preceded by local pains, by abdominal colic, or hiccago, or even by more general symptoms, such as head-ache, giddiness, palpitations, and even febrile excitement; all of which yield altogether from the time that the flux becomes properly established.

At the beginning of many acute diseases a febrile condition may be observed; it may be, and mostly is, unaccompanied with any local manifestations whatever; but we find it in measles and scarlatina, attended with bronchitis and sore eyes when the former, angina when the latter, is imminent. The antecedent fever may, in marshy countries, assume an intermitting form at first, but after three or four paroxysms it becomes continuous, and some local signs appear by which the diagnosis may be to a certain extent pointed out. The simultaneous appearance of local symptoms and of febrile excitement is perhaps the most common of the various modes we have enumerated.

In some diseases the incipient stage has a remarkably uniform aspect, as in eruptive fevers, for instance; in others the reverse is the case—witness typhoid fever.

It is practically of considerable importance to study the incipient stage of chronic maladies. They may succeed to acute disease, or at once set in under their chronic form. In the first case, convalescence is erroneously supposed to have followed the acute disorder, but the error can be recognised by the absence of appetite, the occasional chills, the loss of sleep, and the persistency of weakness: the local signs gradually reappear, and then the chronic malady becomes evident. When chronic affections have not followed acute disease, their origin is often very obscure, the local symptoms by which their first development was attended being neither continuous nor well marked, but the general health of the patient clearly declines. When, without any appreciable cause, this gradual decay is observed, you may be certain that some local lesion is present, which patience and attention will lead you to discover. The first period of the appearance of chronic disease often escapes detection, so insensible are the degrees, which have intervened between perfect health and confirmed illness. Let us, to illustrate the assertion, throw a rapid glance over the incipient stage of several chronic disorders.

Consumption very rarely follows acute pneumonia. Some patients have since their first infancy had what is called a delicate chest; they have always coughed more or less, and been troubled with oppression; others, on the contrary, have enjoyed perfect health up to an attack of bronchitis, which never ceased since its first appearance; but previously they had never coughed. For others, hemoptysis is the first symptom which directs the attention of the patient towards the chest. Not that we believe this hemoptysis to be the cause of the development of tubercular matter in the lungs, but the result of the progress of tubercle which had not hitherto betrayed their presence by any symptoms whatever. In a fourth series of cases you will observe an acute febrile bronchitis, ceasing the rapid and galloping development of pulmonary consumption.

The incipient stage of emphysema of the lungs is also extremely variable. In some cases it is congenital; but in most instances it is the result of prolonged and violent bronchitis, during which the repeated efforts attendant upon cough have distended or lacerated the air-cells.

Diseases of the heart may also be congenital, or may set in with such a slow and gradual increase of symptoms that their exact origin cannot be traced. In some cases organic affections of the orifices follow acute pericarditis or endocarditis, complicated or not with articular rheumatism. We may here mention that it is of extreme importance in the progress of rheumatism not to

mistake the anemic souffle resulting from veno-section, with the souffle produced in the heart by its participation in the rheumatic symptoms. The distinction can readily be made by auscultation of the carotid arteries, in which the anemic souffle is constantly propagated, and not the souffle depending upon pericarditis or endocarditis.

How various are the incipient symptoms of organic disease of the stomach! Some patients die with a cancer of the viscous, who for years have suffered only from insignificant dyspepsia; in others, violent gastralgic pains seem to accompany its first development, and so doubtful is the exact time of the commencement of organic change that it may fairly, in many cases, be asked if the pain was a symptom of the textural alteration, or if it was not its cause.

D. McCARTHY, M.D.P.

EXTRACTS FROM PERIODICALS.

Exhibition of Asafoetida during Pregnancy.—Dr. G. Laferla, of Malta, recommends strongly this substance in doses gradually increasing from two grains to ʒj. daily, for the purpose of preventing the death of the fetus in utero. The cases which Dr. Laferla particularly points out are those in which before labour the fetus ceases to live without any appreciable cause—a circumstance which sometimes shows itself in several successive gestations. Dr. Laferla reports several cases in which the patients had two, three, and four times been delivered of still-born children, and afterwards, under the influence of asafoetida, gave birth to living infants.—*Revue Medicale-Chirurg.*

Acetate of Lead in Spinal Irritation, and in Diseases of the Heart.—In these two orders of diseases, Dr. Salgues has found acetate of lead of the greatest utility, in doses varying from two to six grains daily. In cases of hypertrophy of the heart, palpitations, which had resisted several methods of treatment, yielded rapidly to a few doses of the saturnine salt. *Ibid.*

REVIEWS.

On Wounds and Injuries of the Abdomen and Pelvis; being the Second Part of the "Lectures on some of the more important Points of Surgery." By G. J. GERRARD, F.R.S. London: J. Churchill; 11, Renshaw. 1847, 8vo., 73 pages.

The important class of wounds of which these lectures treat are amongst the most trying and difficult that fall under the observation of the medical profession, in consequence of the importance of the parts injured; the difficulty, in many cases, of ascertaining the precise nature and extent of the injury inflicted, and of applying such remedies as, in other situations, would be accomplished with comparative ease; and, lastly, the variety, not only in the injuries themselves, but also in the constitutional shock and general symptoms which ensue.

Unlike most other injuries, the extent of which has usually some relation to the symptoms which follow, the most trifling of these frequently prove fatal, whilst the more extensive and apparently serious often progress to a favourable termination, without a single bad symptom.

In the present state of our knowledge of the physiological and pathological phenomena attendant on the morbid actions of the animal economy, we are obliged to refer these apparent anomalies to a peculiar idiosyncrasy attached to the constitution of the person injured, without being able to trace out the cause of such idiosyncrasy, which, if it exist, can be but the effect of a peculiarity of constitution, dependent on a corresponding peculiarity of physical structure.

Wounds and injuries of the abdomen and pelvis require much care and attention, in all their stages, from their first occurrence to the final termination, either in recovery or death.

To all of these Mr. Guthrie has directed his attention, and on all has afforded much of that sound practical information for which all the works of this eminent surgeon are so remarkable.

His condemnation of the use of purgative medicines, in the early stages of these injuries, is peculiarly valuable, as this most injurious practice is not yet exploded from the profession. What practice can be more fatal, in cases of wounded intestines, than the exciting of these to motion, by the use of purgative medicines, when rest is so essential, in order to avoid, if possible, the escape of the intestinal contents, and to allow of those conservative adhesions so industriously formed by nature for the preservation of the life of the individual, and the ultimate restoration of the integrity of the intestinal tube?

In treating wounds of the intestines, Mr. Guthrie prefers the continued suture, as recommended by Dupuytren, and advises "that the needle be carried through the cellular fibrous lamella, or between the muscular and mucous membranes, and not across all the tunics." (P. 25.) He also recommends that the sutures, when used in wounds of the abdominal parietes, should be carried through the skin only, and not through the muscular fibres, which he is disposed to think never unite, thus leading in most cases to the future formation of a hernial tumour. His observations on this subject, and the absorption of the muscular tissue of the abdominal parietes, subsequent to blows or other injuries, are both interesting and valuable.

Mr. Guthrie enters very largely, indeed much more largely than their merits deserve, into the various plans that have been recommended by the ancients for the treatment of wounded intestines, by means of tubes, tracheas of animals, and other substances, introduced into the cavities of the intestines. It may be well questioned if the notice of such foolish contrivances may not be prejudicial, as tending rather to distract the minds of practitioners from, than direct them to, the more simple methods now adopted for the treatment of these accidents, and which consist in little more than sewing the wounded parts together, and leaving their subsequent care to Nature, who has proved herself more competent to the task committed to her charge than art has been.

The greater danger attendant on wounds of the small than of the large intestines has not escaped Mr. Guthrie's observations. To this difference many circumstances contribute, namely, the more fixed position of the large intestines, their less relation to the peritoneum, and their inferior organization, which renders their injury less capable of giving rise to that constitutional depression and irritation, so remarkable where the small intestines have been wounded.

We cannot altogether agree with Mr. Guthrie's treatment of hemorrhage, in the interior of the abdomen; the practice of keeping the external wound open, in order "that the blood may have a ready vent," is most questionable, as the continued exposure of the peritoneal surface, thus rendered unavoidable, is productive of more serious injury than can possibly result from the closing of the external wound. It is true that, in some instances, this latter practice is followed by effusion of blood into the abdomen, and distention of this cavity; but what is more likely to put a stop to the internal hemorrhage than the pressure thus induced, especially if aided by the additional support of adhesive straps and bandage, where that may be resorted to? Any bad symptoms that should ensue may be treated as well after as before this method has been tried.

Mr. Guthrie evidently thinks lightly of exposure of the abdominal cavity, and regards "the admission of air—the bugbear of the olden time—as of no consequence." (P. 8.) In this opinion he is not supported by the best surgical authorities of the present day.

The fifth lecture, on Artificial Anus, will be

found to contain an account of most of the plans hitherto recommended for the treatment and cure of this troublesome affection, and the general failure of every one of them. In this the restorative process of nature is certainly more efficacious than the ingenious inventions of either the ancient or modern surgeons. Mr. Guthrie leaves this, very judiciously, an open question, contenting himself with making some valuable remarks on its general treatment.

We should hail with pleasure the appearance of any work on these most serious affections, still, alas! the opprobrium of surgery; and therefore feel much gratified in finding that one of the leading surgeons of the present day contributes the result of his extensive experience to the improvement of the healing art, and the alleviation of human suffering.

As the use of the knife, unhappily, affords us, nowadays, so many instances of wounds of the abdomen, we strongly recommend to all practitioners a work which may be referred to on all such occasions with confidence, and consulted with much advantage.

We cannot refrain from extracting Mr. Guthrie's synopsis of the treatment to be observed in such cases:—

"The treatment of all these injuries must be eminently antiphlogistic, principally depending on general and local bloodletting, absolute rest, the greatest possible abstinence from food, and, in some cases, from drink; the frequent administration of enemata, and the early exhibition of mercury and opium in the different ways usually recommended, with reference to the part injured."

A Detail of Experiments proving the Identity of Cowpox and Smallpox. By JOHN BADCOCK, Chemist, Brighton. 12 mo., pp. 78.

This work is purely practical in its nature; and the investigations contained in it are somewhat of the same kind as those pursued some time ago by Mr. Ceely, of Aylesbury, whose valuable monograph found a place in the "Transactions of the Provincial Medical Association." The fact has long been known and lamented, that the vaccine virus, in consequence of the many and various systems through which it has been transmitted, has lost much of its protective powers, and that it affords, even at the best, only temporary security against the ravages of smallpox. It has frequently been thought desirable that fresh matter should be taken from the cow; but it is one thing to speculate and advise upon this matter, and another practically to proceed with it. Mr. Badcock, however, choosing the shorter and more certain, though difficult, plan of direct experiment, proceeded at once with the business of obtaining virus fresh from the cow; and the results of his valuable researches are contained in the pamphlet before us.

He conjectured, as others have done, that cowpox is only smallpox modified by the nature of the animal in which it is generated. He therefore concluded that, if a cow were inoculated with smallpox matter, the resulting pox would be genuine vaccine. He observes:—

"In the month of December, 1840, I commenced operations on a fine young cow, with smallpox matter taken from a strong healthy girl, and was singularly successful. My own little boy was first vaccinated from the cow, and from this and subsequent operations I have carefully kept up the supply of vaccine. In these proceedings the utmost caution was observed for the public safety, as well as to make the experiment interesting to the profession. Three days after inoculation with smallpox the cow was inspected by medical men; the vesicle was watched in its progress, and the lymph taken in their presence. I also placed all my early cases of vaccination under the inspection of medical practitioners, and a great number of them visited my little boy during the progress of the disease." (P. 16.)

"I have already remarked that my own little boy was the first human being whom I vaccinated with the lymph which I obtained from the

cow. The operation was perfectly successful, and one of the medical gentlemen who had witnessed the development of the vesicle upon the cow became desirous to vaccinate his child from mine. Notwithstanding the unanimous opinions of all regarding my child's case, I thought it advisable to subject most of the patients of the first and second removes from the cow to the same scrutiny: the results were equally gratifying. Good vesicles were produced, and the children did not appear to suffer more constitutional disturbance than is usual from the ordinary vaccine." (Pp. 17, 18.)

"Up to the period of the experiments performed by Mr. Ceely and myself, I believe there is no authentic record of an individual in this country having succeeded in inoculating the cow with smallpox matter; but I have already shown she may be so inoculated, and that a vesicle thus produced yields a fluid which, being transmitted to the human subject, produces all the appearances which Dr. Jenner has described as the true vaccine vesicle; thereby demonstrating the identity of the two diseases, and that, notwithstanding the several points of dissimilarity, they are indeed the same—that cowpox is smallpox which has passed through the constitution of the cow, having lost its infectious qualities, but retained its protective power. This demonstration of the identity of the two diseases establishes the protective power of vaccination upon a substantial basis—proving, that as one attack of smallpox will prevent a subsequent attack, so will vaccination, for they are the same disease; and this identical nature of the two will afford a rational explanation of the protective virtues of the cowpox." (Pp. 22, 23.)

These extracts show the chief features of the monograph of Mr. Badcock, and they are sufficient to entitle him to great praise for the meritorious manner in which he has pursued a most difficult but a most important subject. Many communications from eminent practitioners are appended to his pamphlet, all testifying to the complete success with which he has conducted his admirable investigations.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

March 9.—J. M. ARNOTT, Esq., F.R.S., President.

ON CYANURIC LARYNGE, OR ACUTE ORBITAL INFLAMMATION OF THE LARYNX.

By G. BUDD, M.D., F.R.S.

The chief object of the author, in this paper, is to show that the disease known to practitioners under the above title is really erysipelas, commencing in the fauces, or in their neighbourhood; and that it has been generally supposed to be confined to the larynx, and has been termed laryngitis, in consequence of its often proving fatal before the erysipelas has had time to spread far from this part.

In support of this view, he relates five fatal cases of this disease that have recently occurred in London: one in his own practice, in King's College Hospital; three in the Dreadnought, the particulars of which were given him by Mr. Hudson; and one in Charing-cross Hospital, under the care of Mr. Avery, the particulars of which have been published in the medical journals.

These cases, the author observes, were clearly examples of the same disease, but they did not all begin exactly in the same manner. In three, the inflammation commenced in the fauces; in one, it commenced in the parotid gland; and in one, the first appearance of it was an erysipelatous blush at the angle of the lower jaw.

In all the cases, the inflammation soon spread to the glottis, and produced there the same effects—namely, redness and great thickening of the epiglottis, and of the lips of the glottis, with effusion of sero-purulent fluid in the submucous cellular tissue—to such a degree as, in three of the cases, to produce almost sudden closure of the glottis, and consequent suffocation.

In three of the cases, in which death occurred within a few hours after the inflammation of the glottis came on, and within twenty-four or thirty-six hours from the commencement of the malady, the inflammation had not time to spread far, and the air-tubes and lungs, and other organs, were sound.

In the other cases, which were more protracted, the inflammation had spread down the air-tubes, and there were marks of inflammation in the chest, and an infiltration of a sero-purulent fluid in the loose cellular tissue of the neck.

The occasional connection of laryngitis with erysipelas was noticed by Dr. Cheyne in his article on laryngitis in the "Cyclopædia of Practical Medicine;" and again by Mr. Wood, in a paper published in the seventeenth volume of "The Medico-Chirurgical Transactions." The first person to treat expressly of it was Mr. Ryland, of Birmingham, in his work "On Diseases of the Larynx."

The author cites the facts related by Mr. Ryland, and observes that they prove conclusively that inflammation of the larynx, causing great swelling of the lips of the glottis, and infiltration of fluid in the submucous cellular tissue, and thus leading to speedy suffocation, occasionally results from the poison of erysipelas.

He considers the following circumstances favour the opinion he has expressed as to the nature of the disease:—"That the inflammation spreads in the same mode as in erysipelas of the skin, presenting the deep redness and swelling, and infiltration of a serous or sero-purulent fluid, which occur in that disease; that it is more fatal than ordinary laryngitis; and that it occurs most frequently amongst the inmates of hospitals in which erysipelas prevails, and amongst such of them as are peculiarly liable to erysipelas—viz., convalescents from continued fever or eruptive fevers, and those labouring under secondary syphilitic ulcers.

The author concludes with suggestions respecting the treatment of the disease, and some general remarks on erysipelas.

TO CORRESPONDENTS.

THE MEDICAL TIMES may be procured by an order on any Newsmen or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carfrae, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 13s.; Quarterly, 6s. 6d.

A HANDSOME PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 5s. An allowance is made to the trade.

Ulverstone.—We know of no "analysis of ether when mixed with carbonic acid."

J. D.—The new Irish poor-law, so far as it respects the appointment of medical officers to unions, is not retrospective.

B. L.—The great authority on respectable physiology is our overlooked but distinguished Brown. Lindley's books bring us down to the latest discoveries in this interesting subject.

Mr. Price, of the Waterford Dispensary, sends us a report of a distressing case of asthma, cured by the inhalation of ether. Mr. Price may have the number he requests by ordering it of the publisher, and remitting postage stamps.

Mr. Smith, Belper.—We shall be happy to receive and consider the papers.

Truthseeker's paper is left for him at the office. We do not undertake, as a general rule, to preserve and return rejected contributions.

We are sorry we cannot find room for Mr. Duffin's long case.

Mr. B.—There is no doubt that such persons would be admitted to register, if any such bill were passed.

"The Silent One," who describes a billiard adventure to us of some gentlemen "who are in the habit of drawing if they win, owing if they lose, and chalking up for the tables," has sent us a medical case certainly, but not one fit for our columns.

C. H. S.—Mr. Childs has written a good book on the subject. It is also fully treated of in the lectures of Lawrence and Lallemand, published in past volumes of the Medical Times.

M. D.—The numbers of the last five volumes of the Medical Times are never allowed to be out of print.

H. D.'s letter should be sent to the Army and Navy Gazette. We are, we need hardly say, highly gratified by our correspondent's compliments.

We have also to acknowledge communications and letters from Mr. Beet, Ashford; Mr. Williams, Swansea; Dr. Taylor, Askeaton; Mr. Charles, Colclyn; Dr. McKeag, Coleraine; Mr. Rock, Castle Blaney; Mr. Flewett, Birmingham; Mr. Blake, Galloway; Mr. Elliott, Tresillian; Mr. King, Stratton; Mr. Thompson, Edinburgh; Mr. Ricketts, Droitwich; Dr. Woodham, Ashton-under-Lyne; Dr. Flynn, Clonmel; Mr. Kemp, Wakefield; Mr. Martin, Stonehaven; Mr. McNab, Epping; Dr. S. Palmer, Birmingham, &c.

Ireland's two questions are both unanswerable by us.

The cases by Mr. Martin of Highworth, and Mr. Brown of Castle Dormington, have been received.

We have received the prospectus of Mr. Hansard's new Journal, and wish it success.

The gentleman who comments so freely on the meeting at the Craven Hall public-house, Drury-lane, London, in honour of the West Middlesex Coroner, should have given his name.

A Constant Reader.—During a delirium the ruling passion gets free rein, and hence we suppose the incessant raving about "libels." It is the old wonder—the Gracchi complaining of sedition.

An immense quantity of correspondence must lie over till our next number.

A Correspondent informs us that John Roberts, Esq., M.D., Carnarvonshire, and Christopher Fryer Curtis, Esq., Rio Janeiro, South America, were admitted members of the College of Physicians on Saturday the 20th inst.

Mr. Edmonds remarks to us:—"We find that the heart, in propelling its blood from its left side, causes at each contraction the peculiar sensation known by the name of the pulse, along the course of all its large arteries; and for a like cogent reason it must, I think, be allowed that the other side of the heart (its right side), during its contractions, must also cause a pulse along all the large vessels emanating from it."

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the SCIENCE of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract love of a pedantic and inapplicable lore. Every power of his mind is engaged: he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate, to be EXPERIMENTED: each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diploma or license.

Six of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is *bonâ fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, MARCH 27, 1847.

AN INCORPORATION OF GENERAL PRACTITIONERS.

EVERY hour is impressing us with the deeper conviction that the best foundation of any reform of the profession must be the incorporation of the general practitioners on liberal and comprehensive principles. The "pure surgeons" have their charter: the physicians are expecting, not without hope, an amendment of theirs: a bill, therefore, which does not set out with a charter for the great mass of the medical community would be one-sided, unequal, deformed, hopeless. It would strengthen the physicians in their exclusive privileges; it would confirm the injustice of the Lincoln's-inn innovations, and force on us a legislation which, without that preliminary, we cannot even begin to treat about honourably, much less arrange satisfactorily or fairly.

The charters, given or giving to the two weakest sections of the profession, may be revised or improved by an act of Parliament. But if we have an act of Parliament beforehand, and then have to treat for a charter, we shall at best only get what opponents do not think it necessary to oppose, and that little, whatever its advantages, will be unconfirmed by statute.

Let all the divisions have their charters: they will then stand on equal grounds, and a basis is laid on which the fabric of Medical Reform may rest at once respectably and safely. Adequate machinery for every requirement of medical government will then lie at the hands of the legislator, whether his aim be to educate, to examine, or to secure respectable practice. For every want there will be a supply—for every action an agent.

What would be the effects of a Charter of Incorporation to the General Practitioners? is a question that here naturally occurs to us. The first effects will be the bustle and importance and improvements of self-government. There will be a new ambition generated—that of standing high in the body of general practitioners, and so obtaining their corporate chiefships. From this source more than one important result will flow. Men standing high as general practitioners will feel less temptation to give up their order and betake themselves to the higher rank of pure surgeons or physicians. Their own body will offer them

sufficient inducements to remain; and thus it will obtain two advantages—a greater *éclat* with the public, and the possession, within its own circle, of a class ready, if need be, to act as consulting practitioners.

Yet, to rise permanently in popular estimation, and to upheave their own best men into the position of consulting authorities, it will be necessary that the examinations should not be of an inferior character. What will a charter do under this aspect? If it leave the examinations under the control of the new corporation, independently of the Colleges of Surgeons and Physicians, all will go on well for the body itself, and for the public. With a less protracted term of study, and lower price of admission fee, they might yet make their diploma the most respected in the country. Thus they might have two examinations instead of one, hold both in public, secure the best examiners in the country, and enforce a more practical character into the examinations. Such guarantees would be sought by candidates, and held in estimation by the public.

What then would be the position of this new corporation, with distinguished examiners—respected examinations—a respectable Council—and an immense body of members? Must all who dispense their own medicines obtain its diploma? In that case it would have necessarily nine-tenths of the examinations of the kingdom, and, as it is easy to see, would be, in fact, the head of the whole medical profession.

Such a condition would beget new relations with both the Colleges of Physicians and Surgeons. They would become, in the course of time, corporations incorporated: instead of being of the profession, they would be *in* it. With a community of interests there would be a community of action; and utilities would be derived from their conjoint action which we should look for in vain from their present feeble, detached, and unsupported efforts.

ETHER INHALATION.

"In vitium ducit culpa," *sagax.*"

We have always had our fears that the undoubted utilities of ether would be forfeited through the faults of reckless experimentalizers and the blunders of ignorant pretenders. Medicine, in its advances, has had more to struggle against the bad practice than even the bad theories of its professors; and many a valuable discovery, perfect in principle, has been immolated by the indiscreet or ignorant zeal of those who have been charged with its application.

The first to introduce ether into general use in this country, we for weeks congratulated ourselves on the immunity it seemed for some time to possess from this law of medical science. Successes were for months the rule: failure or accident the exception. Some of the most remarkable operations known to surgery were performed without the slightest sensation of pain; and this, too, while the varied construction of the apparatus, the novelty of the agent, and a rather general ignorance of its chemical and therapeutical qualities, made the chance of ill-success far from improbable. Latterly, however, with growing experience we have had

deteriorated results. Three deaths are already on record; numerous serious accidents of a less fatal character are spoken of as common. In France a reaction has taken place as strong against ether as was the bias originally in its favour; in England it is beginning to be viewed with considerable distrust and suspicion; and in the canton of Zurich a state order has altogether forbidden its use, until its safety be better ascertained. In fact, at this moment it is a question in all men's minds—is not the use of ether in operations too uncertain and dangerous a resource surgically to be had recourse to? Should not the "great discovery of the age" be forthwith abandoned? In other words, ether has been so discredited by the blunders of its partisans that it runs the peril of many a preceding boon of medicine—as hasty a proscription as it secured, in the first place, a zealous adoption.

Now, it is our privilege to contend that ether, while it is neither so magical nor safe as some zealots would describe it, possesses in prudent and enlightened hands clear and incontestible advantages which should for ever attach it to medicine as one of its most valuable and precious adjuvants. It is not, nor ought it ever to have been supposed, an agent without danger, under all circumstances. It is a law of nature, that whatever is greatly valuable in its use must be proportionately mischievous in its abuse; and it is impossible to survey the powerful effects of ether on the human frame—producing a total revolution in the whole physical and, we may add, psychical system of the patient—without feeling that the extremity of beneficial influence beneath our eyes must be lying very near the confines of that power which wields the sceptre of lethal disease and death. But it is the distinction of the true physician that out of the nettle danger he plucks the flower safety—that he can advance to the very boundaries of peril to secure the elements of conservation; and that, though the right path be narrow, his knowledge and skill enable him to walk it with as much certainty and assurance as though it were the broadest and safest highway. If we look at the late unfortunate case at Grantham, we shall find grounds for the belief that, had the patient been in the hands of any one well acquainted with the use of ether for operations, the poor woman might, *as far as that agent's influence was concerned*, have been alive to-day: for it should not be forgotten that there was here an operation of an hour's continuance, which, under any state, would make a reflective man hesitate in identifying the *post hoc* with the *propter hoc*, and laying the death at the door of the ether. A fact, too, that at once invites remark is, that the apparatus described as having been employed would seem to possess so few of the indications requisite for the safe use of this agent that a failure could scarcely be deemed unlikely or surprising. It cannot, likewise, have escaped notice that the symptoms described in the report of the inquest by the witnesses examined entirely corresponded with those detailed by Mr. Startin, in our last number, as those characterizing the stage of collapse result-

ing from the patient having breathed the ethereal vapour in "too concentrated a form" and for "too long a time." We direct professional attention to his observations as most important: for compliance with the few rules set down by him seems to us of the first consequence. Every one of them appears to us to have been violated in the deplorable case before us. More rashness, more thoughtlessness, or more ignorance it would be difficult to exemplify in reference to so important an emergency. It behoves the profession, while proceeding in every step with the utmost caution, to examine and severely test the remedy under the varied circumstances for which its administration may be called for, and we invite any communications on this subject which shall add to our daily increasing knowledge upon it. So late as Saturday last we had the opportunity of witnessing two operations, by Professor Partridge, at King's College Hospital, under ethereal influence. The first, conducted with Startin's instrument under his own superintendence, was entirely successful in its early stages; but, though the operation lasted twenty minutes, Mr. Startin did not suffer the patient (a spare, delicate woman, suffering under mammary sarcoma of the breast and axillary glands) to inhale the vapour beyond ten minutes, and, altogether, only to the extent of *half an ounce*. The wisdom of this precaution was afterwards apparent, for so much exhaustion followed the operation that the consequences might have been as fatal as those at Grantham had the ether been breathed in a more concentrated form, or for a period longer than was permitted. In the second case, an amputation of the arm, performed also by Professor Partridge, the patient was not influenced by the ether: the apparatus employed—we do not know the name of the inventor—not possessing the qualities necessary for the safe and sure administration of this agent. As this is an important topic which throws considerable light on the Grantham case, we will enumerate what we consider the requirements of a perfect apparatus:—

1. The quantity of ethereal vapour and air for a single inspiration should admit of being exactly regulated, so that there may not be more than equal parts of air and vapour.
2. Aqueous steam should have the capability of being added to this vapour.
3. Lest the ether be impure, the apparatus employed should possess the means of purifying it.
4. The valves and tubes should be so arranged that the freedom of inspiration shall be interfered with as little as possible.
5. Simplicity should be the prevailing feature in the whole contrivance.
6. The mouthpiece should be so made as to take in the nose, or the means of compressing that organ should be attached, so that one hand of the assistant only may be required.
7. The receiver for the etherized air should be of glass, so that the party administering the ether may observe the progress of the inhalation, and have a hand at liberty to cut off or moderate the supply of ether as required.
8. In no case is the inhalation to be con-

tinued beyond a quarter of an hour, with an efficient form of apparatus; and never more than two ounces of ether in vapour should be inhaled.

These are simple matters, of self-evident propriety; yet we have more than a suspicion that in innumerable instances—one of them the Grantham case—they have been wholly overlooked. People have heard of ether operations, and in their eagerness to gratify the curiosity of their friends, and extend the celebrity of their own surgical powers, have fancied that, the discovery of a willing patient being given, all the other conditions were a mere matter of course. Any ether, in any quantity, in any combination, through any apparatus, would stupify—and, this gained, it was fancied that nothing was to be done but to operate. This recklessness has brought its natural consequences, and we shall feel resigned under them if, instead of wrecking the useful discovery, they rather serve as a beacon to those who are charged as a duty with its safe guidance.

MISCELLANEOUS CORRESPONDENCE.

DR. ORPEN'S REPLY TO DR. HILBERS'S LETTER OF MARCH 6. (Pp. 44-46.) HAHNE-MANIA.

(To the Editor of the Medical Times.)

SIR,—As Dr. Hilbers has not arranged the "experimentum crucis," which I suggested as a test of the comparative value of rational medicine, and of Hahne-mania (as it is now called on the Continent), as to medical men at Norwich, nor as to myself here, it would seem needless for me to answer his letter in detail until he does so.

There are, however, a few points on which I may touch briefly at present.

He acknowledges candidly that all the experiments of Hahnemann and his pupils were made on habitually inveterate smokers of tobacco, both at the time and during all their previous life. Such experimenting, on persons soaked with the poison of nicotine, never could tell anything as to the true effects of other medicines, and especially not of any weaker ones, and in small doses.

As to musk not losing weight by years or ages of odorous effusion, if the experiment had ever been tried by Bell, Muller, Carpenter, or Chambers, they would have given the exact details of the trial. I again assert that no such experiment ever was made; but he cannot expect me to prove a negative. The fact is, that Bell, Muller, Carpenter, and Chambers, only repeat a common error. If his statement, that ten years' diffusion of odour by musk in a room, with a draught of air always through it, did not cause any loss of weight, were true, it would only prove that effluvia does not depend, as he asserted, upon an efflux, with loss of odorous particles, but upon some unseen cause, such as polarization of particles, magnetic or electrical powers, &c.

As to homœopathic dilutions, allow me to translate a passage from "La Lanette Française, ou Gazette des Hôpitaux Civils et Militaires," Mardi, 6^e Octobre, 1846, No. 117; tome viii., 2^ede série (19^e Année), page 1:—

"A German physician, Dr. Schincko, of the duchy of Teschen, published, many years since, at a time when homœopathy was in great vogue in Germany, a work entitled 'The System of Hahnemann Considered and Examined in a Mathematical and Chemico-Geological Point of View.' The book has been translated into French by Dr. Dreyfus; the translation is dated at Moscow, in 1830. This work, which is very little known, however, in France, is very curious. The calculations in it,

made by Dr. Schincko, have, though very complicated, been repeated and verified at the request of M. Aubert Roche, and found perfectly correct by the astronomers at the Bureau of Longitudes at Paris.

"All the world knows that, according to Hahnemann, the series of diluted homœopathic medications is formed of thirty shades or dilutions. The homœopathic pharmacist first makes a range of thirty flasks: into each he introduces 100 drops of water, or of some other diluent; into the first he then drops one drop of some active medicamentary substance, usually of a tincture, and he produces the mixture of this one drop with the 100 drops of diluent previously inserted, by shaking the flask according to certain rules; from this first flask he takes one drop, and adds it to the second flask of the series, containing also, already, its 100 drops of water, and then shakes it similarly; from this second he takes one drop for the third; from the third, one for the fourth; and so on, until he comes to the thirtieth.

"From all these processes there result thirty dilutions of thirty successive centesimal divisions, and each flask in succession contains, of course, one hundred times less of the medicamentary substance than the preceding one; all the thirty flasks together contain only one single drop of the original tincture, very unequally divided too.

"It was absolutely necessary to recal to mind this 'modus faciendi,' in order to understand what follows.

"Dr. Schincko first calculated the quantities of the diluent liquid which it would be necessary to employ to produce thirty similar dilutions, &c. &c., and he arrived at the following results:—

"For the fourth dilution one would require 655 quintals of liquid; for the eleventh, as much as the whole waters of the Black Sea; for the fourteenth, as much as one-third of the globe of the earth could represent; for the sixteenth, as much as 3800 spheres like this earth in size; for the eighteenth, twenty-four spheres as large as the sun; for the twenty-first, twenty-four millions of suns; and, finally, for the thirtieth—that is to say, of that dilution in which the medicament is only given in the decillionth part—the operator would require as much liquid as could be supplied by twenty-four quadrillions of spheres of water as large as the sun, or thirty-three quintillions of spheres like this earth.

"The mass of water, therefore," says the author, "which would be necessary to obtain the division at a decillionth of a drop of the medicine, would form a sphere of which the diameter would be equal to 1,760,000 times the distance of the sun from this earth, or — 900,000 times our distance from Uranus, or — nine times the distance of a fixed star. A ray of light, which in the space of a second travels 41,000 miles, and which, therefore, comes to us from the sun in eight minutes seven seconds, would take twenty-eight years to traverse such a sphere as that described!!

"It would suffice, then, to mix one single drop of tincture of nux vomica with this immense mass of water to be able to give with success a decillionth of this mixture; but, if the atoms of that drop separated from each other with the rapidity of the flight of a cannon ball, it would still require us to wait for 45,000,000 of years before the mixture was uniform.

"Here," says Dr. Schincko, "the question presents itself: how many sick people would Hahnemann say he could cure with a single drop of tincture of nux vomica if he gave it commonly at the thirtieth dilution, or in decillionth doses? It is easy to prove by calculation that this one drop of tincture of nux vomica would suffice for two hundred thousand quadrillions of men! and, if each man took every day one drop of the tincture reduced to the divisional decillionth, there would be consumed every year seventy-three quintillions of drops! consequently, one decillional drop would suffice for thirteen thousand six hundred and ninety-nine quadrillions of years!!"

That such dilutions will cure diseases is what Dr. Hilbers expects us to believe. If he will only allow us a few patients, out of the eight hundred millions in this world, for treatment on the rational

plan we will make him, with hearty good will, a present of the two hundred thousand quadrillions of men, to be treated by his decillionth doses, *in nubibus*.

As to "the vast body of symptoms obtained by Hahnemann, which he describes in his 'Materia Medica Pars,'" and to which Dr. Hilbers refers, I cannot say that I believe it to be a vast body of fancies or of falsehoods; but, if the symptoms produced by each medicine were really as numerous and as various as there stated, both they and Hahnemann's book would be totally useless: for it would be all guesswork, what symptom you were to oppose or to produce, or what medicine to use to induce the symptom wanted, so many, he says, do produce it.

Dr. Hilbers recommends me to attend the "Liverpool Homœopathic Dispensary," where, he says, I should "see 300 persons treated weekly." This would make, according to Cocker, the annual number of 15,000. And yet the late report of the "Birkenhead Homœopathic Dispensary" states, that "in the four years 10,240 patients have been admitted at the Liverpool one." Which statement is true? But 10,240 in four years, or 15,600 in only one? It is as evident as homœopathic dilution of truth, that both cannot. Yet "Dr. Hilbers" and the "Birkenhead" report both state, "300" as weekly treated at the "Liverpool Homœopathic Dispensary." How they make out "this average," they will settle among themselves.

But as to what is to be learned, either there or here, as to their non-treatment, I must say that I have no wish to learn it. Several patients have called on me with tickets, from the "Liverpool" or "Birkenhead Homœopathic Dispensary," and the diseases marked on their paper of receipts were not at all the diseases under which they had been or were labouring. For example, a man came to me some time since, with his disease marked "sciatika," by one of the Liverpool homœopaths, and yet it was not sciatika at all, but "morbus coxæ senilis"; and his left leg was two or three inches shorter than the other, in proof of the fact.

However, it is not by mistakes of this kind—viz., of more severe for less severe diseases—that they usually err, but quite the contrary: for, as they dis-aggregate microscopically their doses by infinitesimal subdivisions, and by dilutions into decillions, so, on the contrary, they exaggerate telescopically the disease which they treat, calling often mere pains "inflammations"; and this is the whole explanation of all the false reports that they import from Germany and Dr. Fleischmann as to the numbers cured by homœopathic non-treatment or ill-treatment, compared with rational treatment, or what they falsely call "allopathy" or "heteropathy."

I could tell Dr. Hilbers the full details of the cases of three persons, whom I know well, who were killed by homœopathy within these two years; and of these, one was the very person who made me a present of a costly homœopathic medicine chest to induce me to try it; and I did so on myself to the very last bottle, as already explained: they were killed by their diseases being wholly mistaken, and also by their time of possible cure by rational treatment being let slip. To oblige one of these, I allowed the homœopathic physician, who had attended my friend in some prior illnesses, to prescribe for me, when ill; I described my case minutely—first personally, and then by correspondence—and did exactly as I was bid, taking medicines that I did not know at all. He was a thoroughly gentlemanly man, well educated, and clever; but the medicines produced no effect. I did not expect they would. I never had faith in any of them.

As to attending a homœopathic dispensary to learn, I should just as soon think of attending a bread-pill manufactory or hospital. Seeing cures of hundreds of cases occur under doses of globules, would only convince me of what I already believe—viz., that multitudes of diseases and illnesses will get well without any treatment at all, or by any treatment in which the patient has faith, and very many more by mere diet and the lapse of time.

Dr. Hilbers says that I have misrepresented his sentiments, misquoted his letter, and jumbled his

words together into new sentences. I say that I did not, and that it is not the fact, or true in any sense; and, as it would be more waste of time to reiterate what he and I had said, let your readers compare and judge if I did not quote truly.

As to tobacco-smoking experimenters on infinitesimal medicines, he says—"Every smoker knows the extreme inconvenience occasioned by breaking through the habit when once formed." As I never smoked, I know nothing personally of this; but, as almost every homoeopathic that I have met thought it right to imitate their master and his German pupils in this dirty custom, perhaps he does. But does he really think that it is only giving up a habit that in this instance causes inconvenience? Does he not know that it is not a mental or moral habit like curling or false reasoning; but that it is a bodily habit, and that the inconveniences and discomfort of abstinence from tobacco—smoked, chewed, snuffed, or plugged, as snuff, cigar, pig-tail, or quid—are caused by the want of the usual quantity of poisonous or narcotic excitement, and an actual chemical difference in the circulating fluids, or in the nervous chemistry of the body? And if so, how can any any tobacco-smoker, while using it, or even until thoroughly purified, judge of the delicate effects of any medicine on himself?

Since you published my letters, I have received a very excellent letter from a foreign physician, who once went to Hahnemann, and put himself as a person in health, and his patient as a person in sickness, under his care, to try if, in his own healthy body Hahnemann could, by medicines, produce the medicinal diseases that he asserted, and whether in his patient he could produce the curative medicinal symptoms that his book promised. In all his attempts, in both the physician and his patient, Hahnemann completely failed. Dr. Hilbers objects to my trial of eighty-four medicines on myself, and says, that I "dishonestly undertook the experiments, without any *bona fide* intention of eliciting truth." Well, he is no judge of my honesty, let him object as he likes; he has not so fairly tried the experiment on himself; but what will he say to Hahnemann's own failure to prove his words in those two cases? I certainly did try to elicit truth; but I confess I never did for a moment believe that truth would issue from a homoeopathic medicine-test; I always disbelieved almost all that was asserted; but yet could not bring myself to conceive that men would assert so many things without any foundation at all.

If Dr. Hilbers tries to show that effluence is caused by a body's losing odorous particles, by proving that, after ten years' loss of such particles, it loses none of its weight. I wish him joy of his physiology, no less than of his reasoning and studies, and only beg that he may not weigh in in his own scales. If he argues that there is a loss of particles, by proving that there is no loss of spontaneity, it is no wonder that he tries to show that diseases are cured by one or a hundred minims, taken from a solution of one drop of tincture of nuxvomica, in a sphere of water equal in diameter to 100,000,000,000 miles: that is, in English arithmetic, one hundred and sixty-nine billion two hundred thousand million of miles. Did it never occur to him, that the proof that he adduces, even if it were a fact, would disprove his own theory? Is it the case in chemistry, mechanics, dynamics, or any other science, that any body loses parts without lessening the whole? Has he, too, ever examined, how much weight musk will lose or gain, by ten years of effluence of odours, or ten years of influx of damp or confluence of dust, in an open room? or by ten years' effluence and absorption of various gases? But this is all beside the point in discussion.

Dr. Hilbers confounds "Hahnemann and his system" with experiments on the precise effects of every single medicine, in every one of its preparations, and in all kinds of doses, both upon persons in all states of health, and in all sorts and symptoms of disease. To this part of Hahnemann's examination of medicinal substances no man ever objected: for it is only part of the common in-

quiries of every medical man, since disease entered the world. But this has nothing in it peculiar to himself; nor has it any necessary connection with his system, or his theory of "similia," &c., of "dilutions," "potencies," "præparata" (or "irch"), nor with infinitesimal abstractions of the ghost of a medicinal unit.

Dr. Hilbers says, "I am not aware that Hahnemann ever said that the effects of an infinitesimal dose of medicine, taken by a person in health, would display its effects for six weeks. Will Dr. Orpen refer us to the work where this assertion is made?"

If Dr. Hilbers will refer to the "Translation of Ernest von Brunow's Glance at Hahnemann and Homoeopathy" (the author of the first French translation of Hahnemann's "Organon of the Healing Art"), "translated from the German by J. Norton, M.D." (my dear neighbour at "31, Hamilton-square, West-Birkenhead, 1st July, 1845"), and published by Simpkin, Marshall, and Co., London, 1845, 8vo., p. 40, he will find at page 27 the following sentence, honestly stated by Brunow, and honestly translated by Dr. Norton, whom I have the pleasure to know and respect:—"Hahnemann, however, was firmly persuaded of the 'potentialization' of every medicinal substance by its attenuation, in the way described, viz., 'trituration and dilution.' (See p. 26.) An entire drop appeared to him to be always too strong a dose, and he directed that 300 globules of milk-sugar, of the size of poppy-seeds, should be moistened with a few drops of the tincture; and he ordered that two or three of these should be taken for a dose. To this extreme smallness of dose he added another extreme, a term concerning the length of time of the action of an individual dose; for he maintained that we must allow the medicines to act, according to the state of the patient, from four to ten weeks, before we repeated the dose. With very little doubt, susceptible patients, he considered even the globules were a dangerous medicinal dose. In such cases he recommended more effluence—the smearing of a bottle, containing globules, that had been saturated with the decillionth attenuation."

Perhaps Dr. Hilbers will favour us with a calculation, how many particles each snuff of each patient (especially snuff-takers) would abstract from the odorous effluence of each such globule, in any such decillionth attenuation bottle; or how many centillions at ages it would take to exhaust one bottle, or the whole of a homoeopathic medicine's stock, or his pharmacist's shop. Dr. Hilbers may say, that the above extracts only relate to sick people, or the word used is "patients," and perhaps it is so; but they may have been only "patients" of medicinal diseases, produced homoeopathically, as well as of real diseases so treated, for anything that appears in these paragraphs. I have not my former letters by me at present to refer to, in order to see if I alluded to "six weeks' effects" or "decillionth doses" in "healthy" or in "sick" persons. But, if such doses act for ten weeks in sick persons, it is scarcely likely that they would not act for but that time in healthy persons.

As to Hilbers's "proving" of medicines, the following extract from the same work, p. 20, gives a laughable account of his manner of trying the effects of them:—"A very peculiar mode of life prevailed in Hahnemann's house. The members of his family, the patients, and the students, &c., lived and moved only in one den, and that was homoeopathy; and for this, each strove in his own way. His four grown-up daughters assisted their father, and each gladly took part in the provings; and still more, this was done by obliging students," &c. This is really written by a homoeopath, and translated by a homoeopath! Only conceive "Hahnemann's four grown-up daughters," and a quaternoon after quaternoon, in succession, of "obliging students," trying the effects of all large doses of every medicine in the same house, and "each striving in his" or her "own way," after swallowing an ounce of salts, or a few drops of tincture of phosphorus.

But I must not trespass too much upon your space at present. I may hereafter send you a few

other remarks on Dr. Hilbers's letter, and on Hahnemannism.

I am, your obedient servant,
CHARLES EDWARD HERBERT ORPEN, M.D.,
Fellow and Member of the Royal College of Surgeons of Ireland and of England.
34, Hamilton-square, West Woodside,
Birkenhead, March 8.

THE BIRKENHEAD CASE.

[To the Editor of the Medical Times.]

SIR,—Much as the death of Caroline Gray at Birkenhead, under circumstances detailed in your last, is to be lamented, I have long been convinced that such cases (I hope one might suffice) must occur, before a proper understanding can be made to exist between the public and the profession in respect of midwifery attendance. The jury, whom I must suppose to represent the public, "regret that more prompt and efficient aid was not rendered by the medical men in attendance." I do not wish to cavil about trifles, but must say that a verdict ought to put in something like consistent and intelligible form. There is not one title of evidence to show want of efficient aid whilst in attendance, for the woman was delivered by Mr. Stevenson. Mr. Steele calls on the Wednesday—can he be said to be in attendance, when he positively stated that he would not attend unless paid his fee, which was not forthcoming? What the jury meant to regret, if they were rational men, was, doubtless, that more prompt attendance was not given. Be that as it may, certain it is that not a word of regret was uttered, that more prompt and proper provision was not made for securing to this poor woman the requisite aid when the hour of need should arrive, of which abundant warning had been given: for labour is not a casualty which comes upon a person unawares; many months are allowed, in which to prepare for all its consequences and necessities. Through a criminal neglect of the relatives in this respect, a woman's life is sacrificed, and a sapient jury save their consciences by throwing dirt at members of the medical profession. Now, Sir, as a member of the profession impugned, with a wife and family dependent upon my exertions for support—my patrimony spent in qualifying myself for practice—I would beg leave to ask the public, am I justified in abandoning that family and such practice as would, by fair remuneration, furnish them with the means of support, and squandering my time and health in attendance upon midwifery cases, without hope of remuneration, till by such a course I become a tenant of the cold grave, and leave them as a legacy to a still colder world and the tender sympathies of a union workhouse, where, perchance (frightful though it appears), they might possibly be driven to allay the cravings of hunger by tearing the rotting flesh from my decaying bones? Or, declining such an asylum, if, as houseless wanderers perishing from starvation, they should venture in the dead of night to arouse the butcher or the baker from his slumbers, and demand his unremunerated assistance in averting their doom, would the public, on their appearance at a police-office the next morning, regret that his prompt assistance was not given to their necessities? or would they laud the public spirit and philanthropy of a man who, by his decisive conduct, consigned them to a cell, where they might receive just as much as would keep body and soul together till they should be brought to justice on so heinous a charge? Let the profession look to this—let the public look to this; and perhaps the latter will become somewhat more economical of its regrets and censure, and turn in its corrective might the maxim, "Audi alteram partem." That the public is charitable, nay, even bountiful, after a fashion, I freely admit; and that the medical profession is more charitable by 100 per cent. I am unhesitatingly

affirm. If there be any class more than another who

"Do good by stealth and blush to find it fame."

I solemnly believe it is medical men: they are charitable, as I could prove, to a degree altogether unjustifiable as regards those dependent upon them. Countless almost are the instances in the present day of misery and privation entailed upon their own, by their profligate benevolence to others; yet, as we have so recently witnessed, the shedding of human blood, or the loss of human life, is still essential to a correct adjustment of the relative position of the profession with regard to the public. The snoring public dreams little, or rather not at all, of the effect of midwifery practice, and its attendant anxieties on the duration of life. A casual expression of pity that a man should be cut off in his prime, without inquiring why or wherefore, carries but little of consolation to the bosom of his bereaved family.

Excuse me, Sir, if I take a liberty in appealing to you, or rather a layman in your establishment. My patrimony gone, I am launched in life to practise my profession. Suppose I recklessly disregard the difficulties I know I must encounter, and neglect, by keeping pace with the advance of science, to fit myself for those emergencies which must necessarily occur. I am hastily summoned to a case of midwifery, surrounded with danger and admitting of little delay. I am suddenly awakened to the inadequacy of my own resources, from my own culpable supineness; and, in this desperate state of things—professional death staring me in the face—I run and knock up your publisher, requesting certain numbers of the *Medical Times*, which might supply information that would save me; this I do without a shilling in my pocket to pay for that which I ought to have provided long before. Now, Sir, though I will grant that he is a humane man, what would your publisher, as a man of business, do in such a case? If he supplied me, I should regard him as a fool; if he only laughed in my face—an easy, good-natured fellow; if he assisted my retreat by an unmistakable *oil a tergo* properly applied, I might curse him in my wrath, but cherish him in my heart as a friend who administered a wholesome rebuke.

Permit me, Sir, to say that I have endeavoured to secure myself from any such sudden professional death, and avoided the necessity of putting myself under an obligation at the hands or toe of your publisher; and, moreover, effected a saving to my family of some 5s. or 6s., by the simple prepayment of one guinea for that which was essential to my *"doing as well as could be expected."* If I had neglected this, and allowed myself to be swept from the stage of professional life, by putting off the evil day, in the hope that it would never arrive, my children pining, nay dying, for want of the necessities of life, could I have been accounted an honest or an innocent man? Would not my conscience have upbraided me with a crime little short of murder? To avert such calamity as this, suppose I am driven in desperation to commit a crime—not of a serious character, but veiled in mysterious circumstances which, if not skilfully unravelled, might give to it the blackest dye, and subject me to the penalty of death—who, in such a case, would think of knocking up eminent counsel in the dead of night, to tender a weighty brief without a fee? Would the jury, in finding me guilty, regret that efficient aid was not rendered by counsel in attendance? And what of the public? That portion of it who can subsist upon the unrequited exertions of others could and would afford themselves a holiday to witness justice avenged on the scaffold; and perchance there too might be found as spectators one whom I had, without reward, assisted in the time of travail, with the offspring which I had saved from drowning in its birth, come now to requite me by lending the light of their countenance, decked in vulgar finery on this occasion.

You, Sir, or your "alter ego"—the legal half

of yourself—might trip me up here by averring that counsel, under such circumstances, would be assigned to me, and, therefore, no such case of legal destitution could occur. I reply, that as assistance is by law provided, no case of medical destitution can occur—no ground for reflecting on the profession can exist; but both you and I know that such cases do occur, and such reflections are cast; and so long as the present system prevails, so long will this odium continue.

*"But folks are often at a stand
When remedies are near at hand."*

Counsel are "retained," medical men "engaged," or spoken to—the difference being that one receives a fee, the other none.

Now, Sir, I would appeal to you personally, as a skilled witness of the advantageous working of that system of prepayment which obtains in the establishment over which you preside, whether by such an arrangement, without obligation, favour, or affection on either side, a much better understanding is not secured, and whether the mutual interests and interdependence are not greatly enhanced? I can scarcely doubt your reply; what, then, is the inference? Why, that a retaining fee, paid to the medical man at the time of engaging him, would secure to the patient those advantages and services which, by a similar proceeding on his part, he is able to bestow with skill, judgment, and ability, tempered to the finest point—viz., on the sharpening-stone of science in its onward progress up to the latest hour.

But how is this practice to be introduced? Have we not societies and associations without end? Take, for instance, the National Institute: could it not effect for the profession what an individual has done for medical journalism? Ay, and find its account therein likewise. I am not at present even a guinea member; but, seeing its energies directed in such a channel, I would stut myself and my children to furnish a donation, of which my children's children might reap the advantage tenfold. I have no right to claim this duty from the Institute more than any other society, even if my views are approved; I simply select it to illustrate the feasibility of such a movement—a sneaking liking, perhaps, putting it foremost in my mind. How many fees thus secured (otherwise hopelessly lost) might be contributed from the midwifery list of the general practitioner towards any institution that could effect such a wholesome revolution; to accomplish which would, I sincerely believe, be to lay the best and broadest foundation-stone of "Medical Reform," which, though it is being blurted through the *lund ore rotundo*, is as yet but a flitting *ignis fatuus—a vox ex praterita nihil!*

To attempt by a little superficial varnish to raise to a healthy standard a profession which will not be true to itself is to me a manifest absurdity. For their encroachments and exactions from the profession people have nought to plead but custom. In obtaining services at a low remuneration, and subsequently for none at all, they of course reason that—

*"The value of a thing
Is just as much as it will bring."*

The Birkenhead jury selected one gentleman to whom to vouchsafe their thanks. Yet I by no means feel satisfied that the excepted gentlemen have cause to regret their exclusion from the compliments, or for self-reproach, in asserting the rights and privileges of their profession, and their immunities as members of society, much as they might deplore in common with others the foolhardiness with which the reckless and improvident will continue to jeopardize their lives. Tyrrell, the first and principal witness, does not state whether she received or expected to receive her wages.

I am, Sir, your obedient servant,

QUID PRO QRO.

ALLEGED MISCONDUCT OF THE FACULTY AT BIRKENHEAD.

To the Editor of the Medical Times.]

Sir,—Your last number contains the report of

an inquest copied from a Liverpool paper; as the account given is incorrect and exaggerated, and reflects unjustly upon the parties concerned, I hope you will afford me room for an explanation.

The facts of the case as concerns myself are as follows:—

"On Tuesday, the 23rd ult., the husband of the deceased came to my house about seven o'clock in the morning, and asked me to attend his wife, who was in labour. I asked him if he could pay a medical man. He said 'Yes,' and that I 'should be paid as soon as it was over.' I then accompanied him to his residence, and found his wife in labour, and attended by a midwife and a nurse. From the appearance of the place, and from the statements of the woman, I was convinced the man was not able to fulfil his promise of payment—in fact, that it was a case for the parish surgeon; but on hearing that they had been twice for the 'parish doctor,' and he had not come, and on the man saying he 'supposed his wife must die because he had no money,' I determined not to leave the woman, and proceeded *without delay* to adopt the means necessary for her relief. Finding the case to be one of unusual difficulty, I deemed it right to hold a consultation with another surgeon, and, having first ascertained that I could safely leave my patient for a short time, I went myself to Mr. Stevenson, the oldest practitioner in the place, and requested him to see the case with me, telling him it was a proper case, and that neither he nor I would get a fee.

"With the readiness he has shown on former similar occasions where I have required a consultation in gratuitous midwifery cases, he kindly returned with me, and rendered the required assistance, and in due time the woman was delivered of a child, still-born and partially putrid, and, not as stated in the reports, 'with one leg off, and much mutilated,' there being only slight laceration of the skin of one foot and arm, from incipient decomposition.

"I visited the woman again the same evening, and on the following day, when she was going on favourably; I then told the friends I should discontinue my attendance, and directed them to apply immediately to the relieving officer for an order for the parish surgeon, who would afford them not only medical attendance, but also food, which was then far more necessary for the patient, and which they had not the means of procuring, nor I the power of ordering.

"I heard no more of the case until Saturday, when the nurse called and told me the parish surgeon had not been, and that the deceased's husband would not go for him.

"I desired her to send some one immediately for the parish surgeon, and called afterwards myself, and ascertained that he was in attendance.

"I have Mr. Stevenson's authority for stating, that he is satisfied that, from the moment I was sent for, no unnecessary or injurious delay occurred, and that the treatment adopted by me was in all respects such as the case required; and, moreover, that he believes the woman's death was not owing to the nature of her labour, but that it resulted probably from her previous habits and her state of destitution.

"I deny most positively having said that I would leave the woman unless I was paid my fee or received some security, or that I had any intention of deserting the patient the moment I was aware of her situation, and the difficulty of procuring assistance from the parish. The reason I transferred the case to the parish on the Wednesday was, because the parties were in want of the common necessities of life, and therefore my attendance would have been of little avail, whereas the parish surgeon has power to order anything necessary.

"A. J. S."

The medical history of the case is briefly this:—On my arrival I found the woman had been in labour twelve hours, the membranes ruptured five hours, an arm and shoulder presenting, pains absent or very feeble. I passed my hand into the uterus, and with great difficulty brought

down one foot, but could not succeed in reaching the other, nor could I with the degree of traction I considered justifiable complete the operation of turning.

Under these circumstances, I sought the advice of my friend Mr. Stevenson, who made an unsuccessful attempt to reach the other foot, and to complete version. The pains had now returned and became stronger, and, as Mr. Stevenson considered that the fetus was sufficiently small to pass in its present position, we agreed to wait a short time, and the uterine efforts increased and the child was expelled, it was partially putrid, and there was, as I have before stated, slight laceration of the arm and leg.

The case presented no unfavourable symptoms up to the time when I ceased my attendance, which was on the second day, when I transferred her to the parish.

I think, Sir, this explanation of the real state of things will sufficiently exonerate me from any charge of neglect in the opinion of my professional brethren, who are the best judges of the merits of such a case, but I cannot refrain from expressing surprise and regret that the coroner, who is a medical man, did not insist upon a fuller investigation into the circumstances of a case where the reputation of members of his profession was at stake, instead of closing the inquiry after examining only two witnesses, and adducing no corroborative testimony to the statements of the woman in *Maria Livers*, whose version of the story was in many points at variance with facts, and moreover, that no satisfactory proof of the cause of death was produced, as this important point was not mentioned in the medical evidence, nor was my *post mortem* made. I have also to complain that I was not examined, and, therefore, the jury had no correct account of a very important portion of the history of the case, it is true I was summoned to attend the inquest, and, until the coroner commenced summing up, was under the impression that my evidence would have been taken, no intimation to the contrary having been given me and certainly before I heard the verdict I never for a moment supposed that my jury could pass a censure upon my conduct as I was quite satisfied I had done all that was required of me.

Another hardship in the matter is this: the local press have published, and thus disseminated throughout the kingdom, the grossly exaggerated and highly coloured accounts of them in omniscient reporters, and thus cast unmerited stigma upon the profession, in the eyes of that large portion of the public which is guided by first impressions.

I am, Sir, your obedient servant,

ARTHUR BROWN, ESQ.

Non-Surgeon to the *Birkenhead Hospital and Dispensary*.

Birkenhead, March 2^d.

P.S. In order to enable you to be more correctly in the case, I send you the published letters of two gentlemen connected with the affair.

[Mr. Steele has evidently been much abused. He was made to give a gratis attendance by fraud, then made answerable as for misconduct for his benevolence, and finally, through the characteristic slovenliness and injustice of a coroner's court, made the subject of the foulest charges and injustice through the whole newspaper press of the kingdom.]

DEPUTATION TO SIR GEORGE GRAY, BART., FROM THE COUNCIL OF THE NATIONAL INSTITUTE OF MEDICINE, SURGERY, AND MIDWIFERY.

The following is an abstract of the report of the deputation, consisting of Mr. R. R. Pennington (president), Mr. Martin (vice-president), Mr. Clifton (vice-president), Mr. Fuller, Mr. Bird, and Mr. Ancill, who waited upon Sir George Grey.

The deputation having been informed that the Government were not prepared to introduce any

general measure of medical reform in the present session of Parliament, strongly urged the necessity that exists on public grounds for legislative interference in medical affairs, with as little delay as possible.

It was stated by the deputation, that a large proportion of the Scotch and Irish graduates, and many members of the Royal College of Surgeons of England, were engaged in general practice in England and Wales, without possessing the license of the Society of Apothecaries—the only legal title to practice as a general practitioner in the above named divisions of the kingdom.

That upon a recent occasion the law officers of the Crown had declined that the individuals so practising were acting illegally, and could be proceeded against by a summary process at the quarter sessions of the county in which the offence was committed, and that, if convicted, the party would be found guilty of a misdemeanour and be punished accordingly.

That an imperative necessity had arisen, in consequence of that opinion, that the Scotch and Irish graduates, and the members of the College of Surgeons of England now engaged in general practice in the above divisions of the Kingdom, should, without loss of time, be either prosecuted or legalized, for that, if persons highly educated were permitted to evade the law with impunity, it would be utterly impossible to prevent persons without any medical or surgical qualification whatever from engaging in practice also, to the great detriment of the health and lives of the community.

That from the number, intelligence, and the important functions exercised by the various classes so described, the best course to be pursued in the opinion of the deputation, would be forthwith to legalize them, and that the easiest and best mode of effecting this object would be to incorporate them in a new institution of collegiate and collective character, and that legislation in this respect should not have a retrospective effect.

That the principle adopted when the Act of 1813 passed the Legislature might with propriety be followed in the present case, and that one other arrangement should be made for the future that would secure a uniform and high standard of qualification in all the medical practitioners of this country like.

That in reference to the negotiations which, in concert with the Society of Apothecaries, were carried on with the late Secretary of State for the Home Department the deputation expressed its opinion that the failure of the measures which the Ministers successively brought forward was owing to the general practitioners not having been duly recognised as an independent body, and that the incorporation having been declined them, apart from a general measure of medical reform. The deputation further adduced the fact in illustration of the difficulties arising from this omission, that the College of Physicians had refused to enter with the committee of the National Association on the ground that this body had no legal existence, although they were at the same time in communication with Sir James Graham by whom they were fully recognised.

That the great difficulty is respects the grant of a charter which occurred in the course of the late negotiations arose from the disinclination of Sir James Graham to advise it without the consent of the existing institutions, that the College of Physicians and Surgeons were founded centuries ago for special purposes, and that their respective councils were bound by oath to sustain the particular interests of those institutions and to carry out the special purposes for which they were founded, that, whatever might be the private opinion of the individual in the councils of those special institutions as to the public advantages of a new college, it was not to be expected that they would be parties to a course which might be regarded as a violation of their allegiance to their respective bodies.

That, therefore, the general practitioners, a

class that has grown up within the last fifty years to its present position as a well-educated and influential body, required an institution of their own, embracing the whole range of medical knowledge.

That in the opinion of the deputation these views could be carried out without injury to the existing colleges, which they were desirous of upholding, and that, so far as related to the Society of Apothecaries, the society had already agreed with the committee of the National Association on the terms of a charter, a draught of which the deputation believed was then lying at the Home Office.

The Right Honourable Sir George Grey, after thanking the deputation for the information they had afforded, stated that he should certainly bring in no general measure of medical reform to which the general practitioners were not concurrent parties, and that he would refer to the draught of the charter alluded to by the deputation.

1. FATAL EFFECTS OF ETHER.

(CORONER'S INQUIRY.)

A case of considerable importance, as affecting the practice lately introduced into the medical world of subjecting persons about to be operated upon to the influence of ether, by causing them to inhale its vapour in order to render them insensible to pain, has just occurred at Spittlegate, in the parish of Grantham, in the county of Lincoln, in which death has resulted from that mode of treatment.

At the inquest the following evidence was given:

Elizabeth, the wife of Nelson Leak, of Spittlegate, mason, deposed that she is sister to John Parkinson, of Spittlegate, hawthorser, who was the husband of the deceased Ann Parkinson, to whom witness was also cousin. That her brother had been married to the deceased about a year and nine months, and she was in a very delicate state of health at the time of her marriage—that is to say, she was what is called a very delicate woman, subject to cold upon the slightest occasion, but was not subject to any particular illness and was not consumptive, as witness believes. That about three months after her marriage she became pregnant, and about three months before her confinement she complained to witness that she had a swelling formed upon her left thigh, which caused her pain and impeded her walking. That she showed witness the place, and she (witness) observed a swelling about the size of an egg upon the under part of the left thigh nearest to the body than the knee, and it caused pain upon sitting down. That she called in Mr. Bentley, a medical man, living at Spittlegate, to attend her, and he saw her, and prescribed linseed poultice, and afterwards brought a plaster, which was applied, and causing great pain it was taken off before he ordered it to be so. That the tumour kept increasing, and Mrs. Parkinson was confined of a boy about nine months since, which was born at its full time, and she did very well, and suckled the child for about six months, when it was weaned. That during the whole of this period she was in good health, otherwise than as she was afflicted by the tumour before mentioned. That during all this time the tumour increased in size, and became a great impediment to her walking, sitting, or sleeping. That in January last she applied to Mr. Robbs, surgeon, Grantham, to attend her. That he did so from that period until her decease. That he ordered leeches, and made several punctures in the tumour, which, however, was not reduced, but rather increased. That, in consequence of this, she wished to have the tumour removed, and wished witness to speak to Mr. Robbs upon the subject, which she (witness) did, and he said he would bring Dr. Turner to look at it. That he did so on Thursday, the 4th inst. That at this time she had seen several reports of successful operations under the influence of ether, but had expressed her wish to have the tumour removed before she

had heard of such mode of treatment. That when Dr. Turner came he said he thought there was no other remedy than taking it away by an operation. That on the next day Mr. Robbs called to see the deceased, and asked her if it was her wish to have the tumour removed; and she said that it was; and it was then determined that it should be taken away, and it was also determined that ether should be applied. That about a fortnight or three weeks before witness had asked Mr. Robbs what he thought of the application of ether, and he said he had no faith in it, but at the time in question he said he had performed an operation on a young man's toe with success, under the influence of ether. That witness, on the Saturday, the 6th of March, saw the young man in question, and asked him how he had felt during the operation; and he said quite comfortable, "that he felt quite like a fool;" and he said in answer to a question, that if he had to undergo another operation he would take the ether. That on the same evening Mr. Robbs administered ether to Mrs. Parkinson, in witness's presence, by causing her to inhale the vapour, in order to see what effect it would produce upon her. That it made her laugh very much, and whilst under its influence she was pinched very severely; and when she recovered from its influence she said she felt quite comfortable, and retained all the "consciousness of mind," but not feeling, but was aware she was being pinched, although she said it did not give her pain. That the operation lasted about ten minutes, but the influence continued about two hours and a half, during which time she was hysterical. That on the following Monday evening she was again subjected to the vapour, when its influence was much more rapid, and she became quite unconscious in a few minutes - in about four or five minutes. That she remained so for about a quarter of an hour or twenty minutes, when she became conscious, but the effect of the ether did not leave her for about an hour. That on her recovery she said she knew all that had passed in the room, though she was apparently unconscious; that she could hear though she could not see. That she was not hysterical the second time. That after this it was arranged that the tumour should be removed the next day, Tuesday, the 9th inst. That she appeared to be in her usual health between the operations of Saturday and Monday; and, on being asked if she felt at all unusual, she said her head felt heavy, which she attributed to her laughing so much whilst under the influence of the ether. That witness asked her, on Monday evening, whether she was determined to have the tumour removed; and she said she was; and witness asked her if she would have so determined even if the ether had not been discovered; and she said she should; this she also asked her on the Tuesday morning, and she again replied in the affirmative. That on Tuesday last, the 9th of March, about noon, Mr. Robbs, accompanied by Mr. Rogers, Mr. Priest, and Mr. Dibben, all medical men, arrived at Mr. Parkinson's, and the operation was performed. That it was about one o'clock that the ether was administered. That the apparatus consisted of a glass jar or globe, with a tube that was made to fit the mouth, and it was applied by Mr. Dibben. That in about ten minutes Mrs. Parkinson was reduced to a state of unconsciousness, when the operation of removing the tumour commenced, and she appeared to feel the first cut, as she made a deep moan, whereupon ether was again applied, but witness is not of opinion that she inhaled much more upon such second application. That the operation proceeded during the time the vapour was so inhaling the second time. That witness cannot positively state whether the ether was again applied during the operation, nor can she state positively whether the apparatus was kept applied to the mouth during the whole time the operation was going on. That Mrs. Parkinson was laid upon her stomach upon a table and witness assisted in holding her during the operation, and was placed at the lower part of her body, and did not,

therefore, see her mouth. That upon every incision made during the operation she moaned, and appeared to feel it, as she struggled and nipped witness's hand; but she did not appear to feel anything when the different vessels were being tied up. That to the best of witness's belief the operation lasted an hour all but five minutes, when she was taken from the table and laid on the bed; she had a little brandy and water before the operation was quite over, which she swallowed readily, and a little more when she was put to bed. That she did not appear to lose much blood, and the wound was dressed after the operation and bandaged, and when put to bed she appeared to be conscious. That shortly after she was in bed witness made her a little gruel, which she took, and said she felt better, but spoke in a very low and faint tone of voice. That she did not appear to rally at all from that time. That Mr. Robbs came to see her in the afternoon and evening, and desired her to be kept quite still. That on the following day she remained in the same low state, and Mr. Robbs saw her more than once, and sent her medicine, which was administered, and a little thin gruel and tea were given her by his directions, which was all the nourishment she took. That on Wednesday she complained of a numbness in both legs and the lower part of her back, and hot bottles were applied by Mr. Robbs's directions, but she was not relieved. That witness asked her if she felt pain during the operation, and she said she did when they cut, but not otherwise. That on the Thursday morning, about twenty minutes past five o'clock, she died without uttering a groan. That from the time the operation was performed till her death she never moved by her own power, but was moved when necessary by witness. That she seemed quite conscious during the whole time from the operation till her death. That Mrs. Heaney, the nurse, was backward and forward in the room during the operation.

William Eaton, of Grantham, surgeon, deposed that on Saturday last, by order of the coroner, he proceeded with Mr. Shipman, in the presence of several other surgeons, to make an examination of the body of the deceased, Ann Parkinson. That on examining the body externally he found an incised wound on the left thigh about six or seven inches long, secured by sutures, on removing which he found a wound, which had the appearance of an operation having been performed upon the thigh. On examining it closely he could not observe that any nerve or large blood vessel had been divided or wounded. That there were four ligatures, which appeared to have been applied to small arterial branches. That there was nothing in the appearance of the wound or of its situation that could account for the speedy dissolution of the deceased, and the operation appeared to have been performed as correctly as it was possible to have been done. That he then proceeded to examine the chest internally, and found nothing unnatural in the appearance of it; the lungs were pervious and appeared healthy; they were a little congested at the posterior part, which witness attributed to the position at the time of dissolution. That the heart was next examined, was healthy in structure, but more flabby or flaccid than usual, and containing rather less blood than usual. The stomach was next examined, and contained a little dark-coloured thick fluid of a greyish colour, apparently gruel, and was healthy, but rather congested at the lower part from the position as above stated. The liver was of its natural size, but paler than usual and softer in texture; the spleen healthy and natural, the intestines also. That he did not think it necessary to examine the kidneys, but then proceeded to examine the head. That the brain was quite healthy, with the exception of the upper part of the anterior lobes, the membranes of which were congested with blood, and there was no effusion in the ventricles. That the blood throughout the body was in a fluid state. That witness discovered nothing in the appearances on or in the body to account for the death under the ordinary

circumstances attending an operation of the nature that had been performed. That the congestion of the brain, in witness's opinion, was caused by the exhibition of the ether which was administered, as also the liquid state of the blood. That in witness's opinion the death was not caused by the shock to the system simply produced by the operation, as the deceased exhibited every appearance of a healthy person, though delicate, and the operation was not in a part at all likely to affect the general state of the patient's health. That in witness's opinion the death of Mrs. Parkinson took place from the effects of the ether which she had inhaled, and the tumour itself was not in that state to cause death, witness having seen it since its extraction. That it is what is called an osteo-sarcomatous tumour, which is of a malignant nature, and calculated to destroy life ultimately. That the practice of using ether in similar cases has been sanctioned by the highest medical authorities, and has been used with success in many cases in the public hospitals, and he himself has operated upon a patient, though he suffered a good deal from the effects of it, but is now getting on well.

Robert Shipman, of Grantham, surgeon, assisted Mr. Eaton in the examination of the body of the deceased, and entirely concurred with the evidence given by the latter gentleman. At the conclusion of the evidence, the coroner, having duly cautioned Mr. Robbs, requested to know whether he was desirous of making any statement relative to the case; upon which that gentleman described the manner in which the vapour had been inhaled, and stated that the operation lasted about twenty-five minutes, including the tying of the vessels, the remainder of the time being occupied by the inhalation and the necessary bandaging, &c. He also stated that he believed the deceased felt as much pain as if she had not inhaled the vapour, as she cried out and struggled at each cut. He then proceeded to read accounts of numerous operations in the public hospitals and other places where the ether had been used with success, and stated that nothing had been done in this case but what had been fully warranted by the practice of the leaders of the profession. He also stated that he had attempted to produce reaction by the exhibition of ammonia and other applications without success.

The coroner then summed up, and the jury, having deliberated a short time, pronounced a verdict, "That the deceased Ann Parkinson died from the effects of the vapour of ether, inhaled by her for the purpose of alleviating pain during the removal of a tumour from her left thigh, and not from the effect of the operation, or from any other cause."

At the conclusion of the case Mr. Robbs stated that he fully concurred in the verdict, as he had no doubt whatever that the ether alone was the cause of death, and it was a duty he owed to the public to say so.

Dr. Little, of Sligo, Physician to the Sligo County Infirmary, addresses us in the following gratifying language:—"I send you a Post-office order for two guineas—one guinea my subscription for the *Medical Times*, which, I am free to say, is the best paper of the kind ever yet published; and, for its manly defence of the rights of the profession, demands the grateful acknowledgments of every member thereof for its able and sincere conduct in the Hounslow case."—[We publish this extract as one of many gratifying proofs of the interest felt in the *Medical Times* by all sections of the medical profession in every part of the empire.]

APOTHECARIES' HALL.—Gentlemen admitted members March 18.—Robert Finch, Robert Kemp Buckell, Geo. Anstice Knott, and James Edmund Curney.

Mr. Phelan, Surgeon, of Dublin, has been re-appointed an assistant poor-law commissioner for Ireland.

MORTALITY TABLE 126

COURSE OF LECTURES ON CLINICAL MEDICINE,

Delivered in the THEATRE OF QUEEN'S COLLEGE, Birmingham.

By SAMUEL WRIGHT, M.D.,

Physician to Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham; Physician to the General Dispensary; Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

Typhoid variety of the fever of 1846; its origin and exit; probable cause; not pure typhus; reasons for thinking so; general features; healthiness of the locality, perhaps, prevented it becoming malignant; sanitary condition of Birmingham; typhoid fever of last year, marked at the commencement by nervous prostration, in what organs this was first manifested; concomitant symptoms; debility of the heart; not always to be ascertained by the pulse; reflections upon this subject; faultiness of the heart's action in the fever of 1846; secondary of the debility of the voluntary muscles; not genuine softening; reasons for thinking so; passive congestion the result of this cardiac debility; lung produced; congestion of the brain and its symptoms; of the lungs; of the liver; of the kidneys; of the mucous membranes; reflections upon the treatment of this fever, special and general.

GENTLEMEN,—I shall conclude what I have to say concerning the fever of 1846 by some observations upon its typhoid variety. This was the most common of any. During the latter part of the summer, and throughout the entire of the autumn of last year, it prevailed to a fearful and fatal extent in this town and neighbourhood. In some instances it appeared to be a sequela of bowel complaint; but in the majority there was nothing to account for its origin or exit; it came, nobody knew how—and it departed, nobody knew why; but its visit was an awful one, for many were the sufferers that fell before it.

As I said, when speaking of cholera, I can only suppose its advent to be due to some atmospheric peculiarity. At least, no special cause or causes could be assigned for it. Age, sex, temperament, occupation, mode of living, residence, and state of general health, had no influence over its seizures—they were made indiscriminately, and found victims everywhere.

The cases of course varied very much in intensity; but even the worst which I witnessed (and I saw many very bad ones), I should hardly be disposed to call *pure typhus*, or perhaps, I should say, *complete typhus*. Most of the characteristic features of this were present in the cases I speak of, but they did not occur suddenly, nor in an extreme degree. There was great anxiety especially expressed in the countenance (almost pathognomonic of typhus); prostration of strength; thinness of the blood, which was generally dark, and often uncoagulable; putrescent tendency; fetor of the breath, and a

cadaverous odour of skin; accelerated action of the heart, with diminished impulse, and sometimes with a remarkable diminution of its systolic sound; a dry tongue, coated with a brownish or blackish fur; sordes on the teeth; low muttering delirium; epigastric tenderness; occasionally purging of dark-coloured matter; dusky urine with a putrid, or ammoniacal smell; petechiae. There were all these things, as you know, and yet I should rather call the fever they characterized *like typhus than genuine typhus*. In the latter these morbid features are manifested much more suddenly and more severely than I ever observed in the fever of last year, and they often proceed to a much greater extent, especially the putrescence of the solids and fluids, than was observable in it; moreover, I never saw a case of ulceration of the bowels in the fever of last year, and the enlargement and inflammation of the intestinal glands were much less conspicuous than we generally see in pure typhus. This, again, I believe to be infectious; but I had no evidence of the fever of 1846 being so. These are my chief reasons for thinking that it should be said rather to have resembled typhus than to have been really such.

Perhaps its immunity from a malignant type may have been owing to the several circumstances which contribute to make Birmingham a healthy place of residence. These are—the elevation of its site, its undulations and facilities of drainage, its sandy and gravelly substratum, its ample supply of water, and the average good living of even its poorer workpeople. These are so many antagonisms of the origin and spread of typhus; and it is likely that to them we owe the gratifying fact of this disease, in its worst forms, rarely appearing amongst us. At least it never occurs here in anything like the virulent form in which it appears, too frequently, in the lower parts of Liverpool, and in the old town of Edinburgh. Nor is it improbable that, if our mild cases could be transported thither, they would not be long in acquiring a deadly malignity.

The typhoid fever of last year was particularly marked by nervous prostration: it was the earliest symptom, and the leading one whilst the disease lasted. This lesion of innervation seemed to be the cause of several of the subsequent features of the malady, especially of the fluidity of the blood, and the tendency to putrescence of the solids and fluids. Anything which exhausts the nervous vigour, whether slowly or suddenly, produces these effects. Animals that have been

poisoned by strong sedatives, that have been killed by lightning, or run to death, quickly decompose, and their blood rarely coagulates.

The first morbid impression, in the fever I allude to, I have no doubt was upon the nervous system, and many, if not most, of the other pathological phenomena, came as *consequences*. In this respect it differed from that typhus which is *communicated*, and in which it is probable that the primary effect is produced upon the blood, and the secondary one upon the nervous system.

The depression I speak of was first shown in the organs of locomotion. The patients complained of listlessness and disinclination to stir, and when walking, or rather tottering, their knees were bent, and were straightened with difficulty. After a time, the brain showed its participation in the general bodily languor, and the ideas became confused, the perception weakened, and the judgment wavering; this was without any evidence of irregularity in the cerebral circulation. There were at this period no false ideas, no phantasies, no watchfulness, anxiety, or stupor; the intellectual processes seemed to be irregular and imperfect, merely for want of energy, just as we see after severe illness, in which the brain has had no share except in so far as it has suffered from the debilitating effects thereof; after profuse hemorrhages, mercurialization, &c.

About this time the stomach failed in its offices: the appetite was generally defective from the commencement, but what food was swallowed was usually retained without difficulty; now, however, the *irritability of debility* was manifested in the gastric apparatus, and, whilst the patients complained of a distressing sense of hollowness or sinking at the epigastrium, they quickly rejected any substantial food that might be given to correct it. In some cases the retching was very severe, and followed by alarming prostration. Shortly the bowels became inert: they acted only when prompted, and their sluggishness was the occasion of a great accumulation of flatus, which distended the abdomen so as to give, on percussion, a uniformly tympanitic sound.

The heart was generally the last organ to show its weakness, but its time at length arrived; and then, in almost every case, a new pathological feature was acquired.

The pulse at the beginning was always quicker than natural, sometimes firmer, and again weaker, than it ought to be. But, as I have

often before told you, you must not trust to the pulse to know what is the condition of the central organ of the circulation: you must listen to the sounds of the heart itself, if you desire to know, from its action, what its probable state is. You may have a pulse in all respects natural, and yet the source of it be the reverse of healthy. This is especially the case if you desire to take the circulation as the test of a patient's strength: if you trust to the pulse for this, it is as likely as not that you will be deceived. You may ply your fingers delicately upon a patient's wrist, dangle mysteriously your watch-chain, elevate your eyebrows, and shake your head—and be no wiser for all this pantomime of pedantry. You may say, "But a man may flourish his stethoscope about a patient's chest, and yet know nothing of what he is doing." This is perfectly true, and I am afraid the fact often meets with an illustration; but, admitting that the stethoscopist understands his business, he is far more likely to be correct in his diagnosis of the heart's condition by listening to its action, than another who trusts merely to feeling the pulse. The arterial beat at the wrist has often been considered satisfactory, at the very time when the heart itself was in process of softening. It is far from uncommon for the impulse of the heart and its systolic sound to be scarcely appreciable, and yet the pulse to be sufficiently distinct at the wrist. Admitting that there was no pericardial effusion, there must have been evidences either of softening of the heart, or great debility of it. Such evidences were often furnished in the typhoid fever of last year, and especially in one case you saw treated in the hospital, of which I will speak shortly.

As I have said, the heart was generally the last organ to show itself affected by the nervous depression under which the system suffered. I think this is usually the case under such and similar circumstances: at least my own experience inclines me to say so. If it be a rule that this involuntary muscular structure is more tardy than are the voluntary muscles in participating in systematic debility (as I believe it is), the provision is one of those instances of wisdom for which the operations of nature are constantly remarkable. Our organs of locomotion, though of inestimable value to our existence, are not essential to it. People have been born, and have lived, without arms and legs; and these organs are often lopped off by accident and in battle, or rendered useless by paralysis, and yet the deprivation is not destructive of life. On the first accession of fever, when extreme weakness of the limbs is the chief cause of complaint, there is little harm in this singly: for the services of these limbs can easily be dispensed with for a time, should it be necessary to confine the patient to bed. Moreover, their ailment is suggestive of its probable source, and thus, when advantage is taken of their early manifestations of disorder, this is often remedied before it has time to extend to other organs less capable of sustaining it with impunity. Thus, we frequently see the debility, characteristic of an accession of fever, confined to the structures of locomotion, in consequence of the malady being being cut short by judicious treatment. In other cases, however, where treatment has been improper, or altogether neglected, or where it has not been yielded to, however good and early administered, an important organ has at last begun to fail in its functions, and upon this a fresh, and commonly a fatal, train of symptoms has arisen.

The organ I allude to is the heart. In the fever of last year, this organ (so far as my own experience goes) never indicated weakness as early in the disease as did the muscles of voluntary motion. At the commencement of the attack, when these were comparatively powerful, its action was firm, and only marked by frequency or irregularity. At variable periods, however, when the fever persisted, either in spite of treatment, or for the want of it—periods varying from five or six days, to two or three weeks—the central organ of circulation evinced signs

of debility. These, as I have said, chiefly consisted in a diminution of impulse, and of systolic sound. In some cases there was a proportionate reduction of pulse at the wrist; in others, this correspondence was wanting. In one or two instances which I met with, the impulse of the heart was quite inappreciable when the hand was placed over it, and the systolic sound was almost inaudible by the stethoscope. I have no doubt some pathologists would have considered these to be examples of genuine softening of the heart (especially as they occurred in very severe and protracted cases of typhoid fever), arising either from actual alteration in the muscular substance itself, or from the interstitial infiltration into it of some morbid fluid. For my own part, I think it was simple debility of the muscular apparatus, owing to an insufficient supply of nervous power. I think so, because the feebleness of the heart's action exactly corresponded with that of the voluntary muscles; because, like these, the condition of the heart improved under stimulant and tonic treatment; and because, I am not disposed to think that, had it been genuine softening, such treatment would have been productive of such marked effects.

Upon this debilitated state of the heart supervened passive congestions of various organs that gave fresh features to the pre-existent morbid symptoms. You will easily understand how this would occur, as a consequence of the *vis a tergo* of the blood being diminished, and its passage along the vessels being correspondingly slow—circumstances especially favourable to local stagnation. To this must also be added the fact that, though the cardiac weakness was shown (as is always the case in these states) chiefly in the left ventricle, yet the right ventricle, to some extent, shared in the condition: for this reason, the current of blood through the pulmonary artery and its branches would be lessened in frequency and force, and it would be likely that some congestion would occur in the right auricle and in the great veins leading to it, and, consequently, in the brain. These two causes—the weakened impulse of blood to the lungs, and the diminished sensibility of the brain—would of course render the respiratory function slower and less perfect than natural; and thus, in the unoxygenated blood, would be found another impediment to due capillary circulation.

Hence, as a sequence of the debilitated heart, came the passive congestions I have alluded to. When the congestion occurred in the brain, the simple irregularity of its natural processes, that I spoke of at the commencement, gave place to actions of a more thoroughly morbid character. There was generally a dull, heavy pain, either across the forehead or about the region of the cerebellum; the pupils were dilated, and sometimes there was a slight inclination of the eyes inwards; grotesque or frightful figures were often seen, as well during sleep as when awake; morbid fears or fancies occupied the mind, and were ramblingly and confusedly expressed in a muttering tone; the waking state was of one of semi-stupor, and that of sleep was marked by its profundity and long continuance. A congested state of the brain was the most common pathological condition secondary to that of cardiac debility. Few cases were entirely without it, and the majority had it almost singly.

Sometimes the lungs became congested: with this state the brain always sympathized. I never met with an instance of pulmonary congestion in the fever of last year, without also finding cerebral congestion as its concomitant. The condition of the lungs was chiefly shown by the respiration becoming shorter and more frequent; the action of the heart laboured and unsteady; frequent sighing, or gasping for breath; occasional short cough, troublesome and wearying, but unaccompanied by expectoration, except in a very few cases, when a little frothy, fluid, black blood was spat up; diminished respiratory sound all over the chest, but especially at its inferior portion, with corresponding dulness on percussion.

Sometimes, again, but more rarely, there was

evidence of congestion of the liver. The extent of this organ, as indicated by percussion, was increased, and its marginal locality was tender on pressure; there was oppressive headache, with extreme anxiety and sickness; pale feces, and scanty, dark-coloured, bilious urine; sunken features; yellow conjunctiva, and general sallowness of skin.

The kidneys, in other cases, chiefly suffered from congestion. Here, there was a dull aching pain across the loins, often shooting down the legs; occasional cramps in these; frequent sickness; difficult micturition; urine scanty, and containing albumen, blood globules, or a brownish red sediment, due to the colouring matter of the blood.

The mucous membranes occasionally became the seat of congestion. In the case of Jones, whom I have before mentioned to you, the buccal membrane first suffered, and his mouth was constantly bloody; then his Schneiderian membrane became swollen and vascular, and there was either a slow epistaxis, or a discharge of blood by the posterior nares, which was afterwards hawked up by the mouth. Next, his intestinal membrane became congested, and he was the victim of pain and purging of blood.

When congestion seized the mucous membrane of the stomach, there was always epigastric tenderness and oppression; more or less nausea; frequently, vomiting of a dingy-looking mucus, of dark fluid blood, or of black grumous matter, seemingly blood altered by contact with gastric juice; the tongue, also, became of a dusky red at the edges and tip.

When the congestion attacked the lining membrane of the bowels, there was tormina, tenesmus, occasional tympany, and discharge, *per anum*, of mucus and blood.

You will understand, from the report I have now given you of the typhoid fever of 1846, that the very essence of it was nervous depression; in many cases, this was the chief manifestation—the constitutional power either recovering itself, or its recovery being effected by remedial means, before subsequent pathological conditions had an opportunity of succession: in other cases, secondary causes came into operation, as I have detailed to you, but still they were subservient to the leading one, and were best relieved by relieving it.

You will anticipate my saying that a stimulant form of treatment, discretionally used, was the most efficacious in the fever I speak of. It was. In my own experience, there was no treatment like it. Perhaps I may speak with some confidence upon this subject, having had, in earlier life, an acquaintance with a very different plan of treating typhoid fever. It was my misfortune, many years ago, to see what bleeding would do under such circumstances. During my preliminary medical education, I was temporarily placed with an individual who thought that bleeding and mercury were the only remedies for this form of fever: the result of the practice I will not detail to you. I forgot it as soon as I could, and I am only too happy in this reflection that, in the Edinburgh school, I was able to escape from my *bad tuition*, by availing myself of a better!

In the fever of 1846, ammonia and wine were the best remedies as a general rule. As the patients were judiciously sustained, so did they rally. The reaction was what was chiefly wanted: directly that *innervation* became restored, the patients might almost be left to themselves. I saw nothing clean the tongue, and moisten it, like diffusible and sustaining stimulants. I ourselves were also witnesses of this fact. The only case in which I omitted this form of treatment, the patient died. I had certain reasons for my practice in this instance, as I will tell you in another lecture—whether right or wrong I cannot pretend to say, but certainly the issue was very contrary to my hopes and wishes.

Nothing balanced the circulation, and distributed the stagnant blood of congestion, like stimulants. General bleeding, of course, was out of the question: I have no knowledge of its

having been practised. Local bleeding was not only useless, but hazardous, except in a very few instances, in which the prostration was not marked. In others, the pulse fell even from leeching, and the greater stimulation was needed to establish reaction. Counter-irritation, by blisters or rubefacients, answered most satisfactorily in these cases.

Mercurials, when called for, were borne in only small quantity, and then only when the preparation was mild, such as the grey powder or blue pill.

Strong purgatives, especially of the hydragogue class, did more harm than good. Gentle aperients were the most useful, aided, when necessary, by stimulant injections of turpentine or assafoetida.

This is all I can say at present concerning the treatment; I must give you its detail more fully in the cases I shall report in the next lecture.

CLINICAL OBSERVATIONS ON SOME OF THE MORE FREQUENT DISEASES OF CHILDREN.

By W. HUGHES WILLIAMS, M.D. (Edin.), Licentiate of the Royal College of Physicians, London; Fellow of, and Honorary Librarian to, the Medical Society of London; Member of the Botanical Society; Lecturer on Therapeutics and Materia Medica at the Charing Cross Hospital; Physician to the Surrey Dispensary, and to the Royal Infirmary for Children.

GENTLEMEN,—I have taken upon myself the duty of venturing to offer you a few remarks upon some of the more important and frequent diseases to which the body is liable during the earlier periods of existence—diseases which, when thus occurring, offer many points of extreme interest, and several of which are marked by peculiarities not observed or displaced by others when the body in its more matured condition is subjected to their attacks. Many important affections also are almost limited to the period of childhood, and hence the study of their various phases and of their natural history must be undertaken in the opportunities afforded by youth. When some of the latter class are now and then observed in manhood, their characters and complications are often very different from those seen to occur at an earlier period of life; the treatment of them will have to vary considerably, and did you apply the experience you gained of them in the study of adults only, to their treatment in children, you would often be very seriously at fault. The affections again to which we are liable in the earlier periods of our life require for their due investigation and treatment the application of principles which in our practice with adults are often but of secondary importance, or entirely inapplicable to their cure. The characters, physical and mental, of the youthful organism stamp specialties of their own upon all aberrations from the proper standard of health in the child; and since, as progressive growth goes on, the body is often endowed with impunity from important maladies, you will not think that I am unnecessarily circumscribing your attention, or diverting it from viewing disorder on a large and comprehensive scale, in thus specially directing it to the study of disease occurring in the first and second ages of man.

When you reflect upon how large a share of your attention, on entering the every-day duties of your future professional career, these maladies will of necessity occupy, how high is the interest attached by the parent to your consideration and judgment of the misfortunes of her child, and how often the characters of the material and mental organization of the future man are derived from the impress stamped upon it in youth, you must confess your inability to perform your avocations with self-reliance, and satisfaction both to the mother and yourself, unless you have learned the necessity of paying the closest scrutiny and attention to the disorders of the infantile and youthful frame.

It must be confessed that in this country we

are behind in that attention which is paid in Franco and Germany to instructing the student of our art, both orally and by book, in the manifold diseases incident to the child. In the former country especially, very great attention has been paid to them, and the *pathology*, more particularly, of these affections has been ably and widely developed. Highly profitable to you as will be the study of the writings of the French authors, yet I must confess that there exists not a class of disorders requiring more practical investigation and direct clinical observation of your own than does this, if you would acquire a proper and serviceable knowledge of its numerous phases and forms. In our own language the works of Evanson and Maunsell, Reece and Underwood, are the proper text-books for your perusal; and I would especially draw your attention to the able papers which have now and then appeared from the pen of my colleague, Dr. West. But the best book for your study will be made up of the *living pages* of the history of the physiology of the sick child, and which, at an infirmary for children, may at all times be conveniently laid open to you for reference.

In offering you the remarks which are to follow, I would wish it to be particularly understood that I have no intention of making them a vehicle for statistical or mere numerical details, of accounts of minute lesional alterations, or for a far-fetched, much-forced, and often practically useless exhibition of *post-mortem* details. They are to be—at least, such is my desire so far as my ability will lead me—essentially practical in their nature and tendency, offered to you with a deep and full persuasion of the fact that the grand and ultimate aim of medicine is to *cure*, and that everything is to be made subservient to that important end. I do not, therefore, intend to dilate of mere curiosities of aberrations, either of a functional or organic kind, but to tell you, so far as it lies in my power, how I think you can best find out an every-day occurring disorder, and treat it by a proper application of the principles either of palliative or curative therapeutics when you have so done. I am one of those who believe, and regret to have to do so, that we are tending too much to the mere elucidation of the transcendentalisms of morbid anatomy and of statistical details, and often losing sight of the grand effort—the noblest prerogative of our art—the endeavour to *treat* a diseased condition of body so successfully that we can restore the sufferer to his former state of health. In the words of M. Dobreyne:—"The Pinelists, the organicists, the anatomo-pathologists, the Broussaisians, the statisticians, the numerists, have all, by the exclusiveness of their particular doctrines and views, stood in the way of, and materially retarded the advance of, sound therapeutic knowledge. * * * The reign of anatomism—that is to say, of necropsies and facts and figures—has nearly come to an end, and medical men now long for something more tangible and more applicable to the every-day duties of a professional life; in other words, they wish to have pointed out to them useful rules of treatment and rational means of cure, instead of endless catalogues of statistic tables and of *post-mortem* examinations."

In the lectures which I shall have the pleasure of addressing to you, I shall follow no particular system; one day I may speak to you of pneumonia, on the next of measles; but I shall endeavour rather to call your attention to the disorders prevailing at the particular time. Before proceeding to notice any special disease in detail, I shall make a few observations which I think may be of service to you as guiding and directing your attention when examining the sick child. When you recollect to mind the helplessness and dependency of such a little patient, the inability of infancy to make known its own sufferings and disorders, the obscurity thus and otherwise induced in discovering the symptoms of important maladies, or related ones, of the nature, cause, and duration of which we can often glean pretty exact information about from more adult persons, you will

see that our means of diagnosis must often be apparently obscure in the extreme. I say *apparently* obscure, because I believe, when once that diagnostic tact is attained—which, analogous to what is often called a *botanical eye* by naturalists, may here be termed a *clinical one*—by careful attention to, and frequent observation of, the general physical appearance of the sick child, you will find the right diagnosis of infantile disorder by no means of difficult attainment. It is true, also, that by experience and frequent observation of her infant, the mother can often be advantageously referred to for information, yet she is exceedingly apt to mislead the practitioner, often giving undue importance to particular signs, and scarcely mentioning others of great and paramount interest, as relates to her child. You will be constantly puzzled in endeavouring to separate essentials from non-essentials in the often elaborate description which the parent will retail to you about the disorder of her infant. It is here that you will find that which I have alluded to as a clinical eye come so greatly to your aid in enabling you to reduce her descriptions and analyse her notions of the malady, so that you may arrive at a satisfactory result. In the case of very young children, of course, we can ask nothing of the patient; from older ones it is often exceedingly difficult to arrive at the truth, the child being sometimes led by a sort of special pleading, either of the doctor or the mother, to answer "yes," or "no," as it fancies it is wished.

Amongst the poor, again, you will particularly meet with obstacles to the satisfactory examination of your little patient, some of which impediments are of a kind not so frequently opposing your exploration of the adult. You will find, for instance, that in very young children it is quite impossible to employ *immediate* auscultation; but the ear must be directly applied to the parietes of the chest; in many cases, such are the dirty habits of the mother and the neglected state of the child, that the odour arising from the effete matters continuously accumulating in the long-worn flannels and other clothes of the child is so disgusting and repulsive that the face of the examiner cannot remain but for a very short time indeed in the position necessary for a proper examination of the respiratory parts. Of course, I am now alluding to children of the poor, who are brought dressed to you for examination, or are at least not undressed, and lying in bed, and whose parents have the habit of loosening the upper parts of the dress and slipping them down below the shoulder-blades, so that the mouth and face of the examiner is often brought into direct contact with the disagreeables to which I allude. In our examination of adults, from our being able to remove the face to some distance from the body, these drawbacks are not felt. Again, the crying and fretful disposition or obstinate behaviour of older children will sometimes put the patience of the practitioner to a severe test. In some cases also, so powerful has the idea taken possession of the mother's mind that her offspring is labouring under some particular disease—such, for instance, as hydrocephalus—that, on making inquiries as to the existence of certain symptoms for the knowledge of whose presence you are quite dependent upon the mother, she will reply in the affirmative, persuading herself unwittingly that they really do exist, whilst, in truth, they have occurred at a distant period, or have been but very slight, or been induced by causes of quite a different kind.

I shall now suppose you seated at the infirmary, and a child of from a few months to three or four years old is brought to you for advice, and that the patient rests on the lap of its mother. By a glance merely of the patient many things are learned. First, observe whether the child is dull and heavy, or comparatively lively; if the latter, no important acute affection can be going on; this may be self-evident; but not unfrequently a mother will tell you the child has got inflammation of the lungs: by this glance you know it has not: If the infant be unweaned,

ask if it can suck well; sometimes it is brought to you hanging at the breast—observe if it can suck continuously—if it is not obliged every now and then to remove its mouth from the nipple; if it is not so obliged, but can continue the action, there is no severe acute affection of the respiratory organs going on. Now, observe particularly these three things—whether the child be lying in a dull heavy condition in the mother's arms; whether the lips be very red, sore, cracked, or the corners drawn upwards; or whether there be evident action of the *ala nasi* during the respiratory act. By observing these three things you gain an enormous advantage. By the existence of the first you are led to make inquiries as to the state of the brain; by the second, to the condition of the digestive apparatus and intestinal canal; by the third, to the air-passages and lungs. I repeat, that by the state of repose, the appearance of the mouth and of the nose, you are told volumes. If the child be lying in the condition I have alluded to, regard particularly the head—notice if it is large, much or little hair upon it, fair or dark in colour, and whether rather large blue veins ramify over the unhidden portions of the scalp. If young, put your hand upon the anterior fontanelle, observe whether it be closed or not, whether flat, rather concave, or very convex. If the head be large, hair scanty, fair, blue veins over scalp, fontanelle unclosed and convex, ask the mother if the child has been constipated, and if there is much vomiting? If the answer be in the affirmative, there can, in nine cases out of ten, be no doubt about the matter—serious disease of a scrofulous character is going on in the coverings of the brain. If nothing of all this exists, but the lips are red, cracked, or sore, the edges retracted, look in the mouth: you will perhaps find the tongue loaded, or red at the edges and point, and elsewhere coated, or there will be aphthoid exudations in the oral cavity; feel the state of the skin, it may be very warm; observe the legs, they may be very now and then twisted about or drawn up to the belly. Ask the mother if it gets very hot towards evening, is thirsty, and the state of the bowels? If these things, or several of them, exist, the patient labours under disease having close connection with the digestive and intestinal lining membrane—remittent fever with its gastro-intestinal complications, and disorders of a like character. If, on the contrary, you are attracted by the quick dilating and contracting action of the *ala nasi*, and by the peculiarly anxious look of the child, and, if the child sucks, by its inability to continue, for long, the action, place your ear against the chest, between the shoulder-blades, towards the base of the lungs, and the small crepitant sound you will hear indicates the severe pulmonary disorder. Now, I only lay down these as very general principles to act upon; I am entirely throwing aside for the moment, mind, the connection and complication of the signs of one class of disorders with another. A child may have intermittent fever with pneumonia, pneumonia with secondary brain complication; but I assert that convex fontanelle, with constipation and vomiting, red lips with hot skin and evening exacerbation, non-breathing with inability to suck long together, are signs of the utmost import, and worthy of your acceptance as guiding principles of great and general value. Again, there are other and very important characters to be caught at a glance, which will guide you in reasoning upon the nature of the particular disorder, as well as upon the general character of the constitution or the diathesis of body, &c. If the child be fair in complexion, the iris and the hair light in colour, and the upper lip swollen, see if there be eczematous disease behind one of the ears, or discharge from the latter; observe the ends of the long bones if they be swollen, the ends of the fingers if they be clubbed, the glands of the neck swollen, or the stomach large; notice whether the tarsal edges are inflamed or congested. If all or several of these signs are present, the child is scrofulous without a shadow of doubt; it may soon labour under tuberculous meningitis, disease of the

mesenteric glands or joints. Perhaps the child is dark in complexion: notice particularly if the eyelashes be very long and rather thickly placed, the ends of them almost lying on the cheek; whether the hair intrude upon the forehead, or the latter be covered by a layer of appressed hairs; examine the arms, perhaps there is much short hair upon them; observe particularly, too, the skin of the back, from the nucha down between the shoulder-blades, whether or not much hair is present there as well; if it be there, the child being also thin, inquire if any relative of the patient have been lost through phthisis, or some other disorder of a tubercular kind; for depend upon it, in nine cases out of ten, the tendency to deposit tubercle is present in that child. It may, even then, be coughing; or, if you examine the chest, the signs of pulmonary tuberculosis may be apparent to the ear.

Again, the child may be very young, relatively small in size, brought to you for some affection of the cutaneous surface; observe if there be eruption on the eyebrows or very near them; breaking out, as it is called, about the nose, with constant snuffles; and whether there be eruption between the nates: if there be, make cautious inquiries as to the possibility of the child having been infected with syphilis.

Lastly, if the child be very young, and very thin, and the mother says it is gradually dwindling and pining away, examine well its countenance—it may look like a little old man or woman; observe the abdomen and legs—the skin about the thighs hangs in folds, the extremities are like little sticks, the belly wrinkled, the integuments spotted, or of a dirty brown colour; the mouth is large, and it opens it and cries in a very peculiar manner. Inquire at once, if the child is being brought up by hand, whether it is fed upon such things as "tops and bottoms," "bis-cuit-powder," "arrowroot," and other farinaceous food, instead of being made to live, as all very young children should do, on food of animal origin; ask if the mother has enough milk, if she suckles it; whether she is subject to exhausting discharges of any kind; or whether she is in the habit of giving her child medicine to "compose" it?

These, as I have told you, are important general principles for your guidance; there are others I might notice, but scarcely of so general a character. If, for example, a child is brought to you puffy about the face and eyes, inquire if it has lately had scarlet fever; if the glands of the neck towards the posterior part be enlarged, examine the scalp, perhaps matted with hair, and see if there be not eczematous or porriginous disorder. The dropsy and swollen glands are secondary disorders. Sometimes troublesome vomiting or diarrhoea is complained of: inquire if the little patient is being fed chiefly upon slops, and of a high temperature; or if the child is being continually harassed in all sorts of ways, under the impression it has got worms, since it gets thin, but eats ravenously; ask if it is confined for long periods together in some public or infant school, or gets anything but slops to eat for days together. If an older female child is brought to you with a crooked spine, and her parents are poor, always ask what they do with her: for sometimes she is converted into a diminutive nurserymaid, and obliged to carry about a heavy fat child upon her arm half the day, for weeks together.

DUMAS ON ORGANIC CHEMISTRY.

No. XVI.

ON THE URINE.

(Continued from p. 93.)

Urinary Calculi.—Among the materials which the urine contains, there are some which are naturally insoluble in water, and which, under certain circumstances, may become deposited within the bladder, or even in the kidneys. Thus, when, in consequence of some derangement in the phenomena of nutrition, uric acid is secreted too largely to become wholly dissolved in the

urine, it separates in a solid form. So, also, with regard to the earthy phosphates, when the urine has lost that excess of free acid which retained them in solution. In certain cases, the urinary secretion, from the alterations effected in it, gives rise to the accidental formation of insoluble products, such as oxalate of lime, or, more rarely, cystine and xanthine. These different materials are sometimes deposited in the pulverulent state, without acquiring any coherence, and are voided by the patient under the form of *gravel*; whilst, at other times, they become agglomerated in the bladder so as to form more or less voluminous concretions, known under the name of *calculi*.

Usually, the urine, when taken from the bladder, is super-saturated with insoluble products, and requires but an opportunity to throw them down. Should any solid body reach the interior of the bladder, it quickly becomes the centre of a calculus. This it is that happens so frequently with the calculous fragments which fall from the kidneys into the bladder; also, with bodies which are introduced by the urethra, or with those which get into the interior of the bladder by means of violence, as musket-balls, &c. This usual condition of the urine explains why vesical calculi almost always have a nucleus formed of some small concretion of uric acid, derived from the kidney. We may also, from the foregoing facts, understand how it is that a calculus, when once commenced, always tends to increase.

The same phenomena occur in animals. If a calculus be introduced into the bladder of a dog, it will quickly become covered with froth layers.

From the earliest period, calculi have attracted the attention of physicians. But it is chiefly to the labours of Scheele, Wollaston, Fourcroy, Vauquelin, Proust, and Marcet, that science is indebted for those precise notions which we now hold in their regard.

The principal materials which we meet with in calculi and gravel are: uric acid, urate of ammonia, ammoniaco-magnesian phosphate, phosphate of lime, carbonates of lime and magnesia, oxalate of lime, cystine, xanthine, silica, and fibrine. Frequently, moreover, these matters are impregnated with mucus, albumen, and analogous animal substances, which serve them in some sort as a cement. Calculi are usually presented under the form of globular concretions; somewhat flattened at the sides. Where there are several existing in the bladder at the same time, it ordinarily happens that the surfaces which have been in contact are smooth, and that the calculus is found in the form of a polyhedron; those concretions which are deposited in the ureters have generally more or less of a cylindrical figure. The colour of the calculi differs according to the substances which they contain: those which are formed of the earthy phosphates are almost colourless; whilst others have a grey or yellow shade, or even a more or less deep brown tint. Their surface is sometimes smooth and polished; at other times it is rough and earthy, and is capable of being broken with ease. Sometimes, also, it presents asperities and projecting angles, as may be remarked in calculi of oxalate of lime.

The specific weight of the different calculi varies from 1.2 to 1.9. Sometimes their size does not exceed that of a millet-seed, and in other cases it attains that of an egg. They have even been found occupying the whole capacity of the bladder, and weighing several pounds. The structure of the calculus becomes a very important point for consideration: sometimes it is homogeneous, more or less compact, and earthy or crystalline; at other times it presents concentric layers, which are arranged around a central nucleus. This remarkable structure becomes very apparent, if we carefully saw the calculus through the middle, and then polish the newly formed surface. Ordinarily, the chemical composition of the different layers varies, while the central nucleus itself may be formed by some body accidentally introduced into the bladder.

Uric Calculi.—Uric-acid calculi are generally

of a brownish-yellow or brownish-red tint; very rarely they are white, or of a straw colour; their surface is partly smooth, and in part formed of nipple-like projections which appear to have been somewhat rubbed down. Their fracture is slightly crystalline; frequently, also, it is earthy. They are formed of concentric layers, resembling one another in their aspect, but differing in thickness, and which give to it a general appearance of wood. We usually find a grain of uric-acid gravel, proceeding from the kidney, or a little inspissated mucus of the bladder, forming the nucleus to the calculus, around which are successively deposited layers of impure uric acid, always mixed with a little mucus, earthy salts, urates, and the colouring matter of the urine. This colouring matter may be isolated by means of acetic acid, which dissolves it. Ether always removes from the uric-acid calculus, as well as from most other of these concretions, some trace of fatty matter.

Uric-acid calculi may be recognised with great facility; they are insoluble in alcohol and in ether; water dissolves but a very slight proportion of them. Caustic potash dissolves them entirely, frequently leaving a slight residue of phosphate of lime, and disengaging a very transient odour of ammonia. The mineral acids, and the more energetic organic ones, as acetic acid, form in this alkaline solution a gelatinous precipitate, which, on washing, assumes the appearance of shining scales. The potash likewise dissolves the mucus which serves as the cement; consequently, it may happen that the precipitate will be soiled with some traces of foreign matters. Nitric acid dissolves the precipitated uric acid. By evaporating the solution to dryness, at a moderate heat, we obtain a reddish-coloured residue, the tint of which may be greatly heightened by exposing it to ammoniacal vapour. Heated in a platinum capsule, uric-acid calculi at first disengage the odour of burnt horn, along with that of cyanogen; after a time, they take fire and burn alone. If they should have happened to contain any alkaline urates, oxalate of lime, or earthy phosphates, we shall find in the ashes traces of alkaline carbonates, caustic lime, or phosphatic salts.

To analyse a calculus correctly, we should first thoroughly dry it; then act on it successively by ether, alcohol, and water, so as to isolate the fatty and extractive matters, as well as the soluble urates. The residue is to be treated by dilute hydrochloric acid, which dissolves the earthy phosphates, and there then remains but the uric acid, which is entirely soluble in potash, and the amount of which is easily calculated by precipitating this alkaline solution by an acid, and then washing and drying the precipitate.

Uric acid calculi are often mixed with a very large quantity of urate of ammonia; sometimes they are almost entirely constituted by this salt. The existence of calculi of urate of ammonia was first pointed out by Fourcroy and Vauquelin. They burn with a flame like the uric-acid concretion; but when dissolved in potash, they disengage a strong odour of ammonia. Boiling water dissolves them more readily than it does the pure uric-acid calculus. The acids remove their ammonia, and separate from them the uric acid; the presence of an ammoniacal salt may, indeed, be with facility ascertained in the liquid, separated from the uric acid. In general, calculi of urate of ammonia are less voluminous than those of pure uric acid; they are formed of concentric layers, and their nucleus ordinarily consists of uric acid.

Calculi containing a certain quantity of urate of soda have been met with, though but rarely. Wollaston has, however, proved that the arthritic concretions are essentially formed of this salt.

Xanthic Calculi.—Dr. Marcet was the first to describe this peculiar formation, which he denominated xanthic oxide. This body presents a very great analogy in its composition to uric acid; its formula is:— $C^2 A^2 H^4 O_4$, and differs from that of uric acid— $C^2 A^2 H^4 O_6$ —only by containing two atoms less of oxygen. This

species of calculus has since been met with by Laugier and Stromeyer. Its exterior may be either smooth and shining, or dull and earthy; sometimes it is of a clear brown colour, and, at other times, whitish. Its fracture presents a brownish-coloured surface, but which is devoid of any crystalline or fibrous appearance. It is composed of concentric layers easily separated one from another; by rubbing, it acquires a smooth and shining aspect. Its hardness equals that of the uric-acid calculus. When exposed to the flame of a blowpipe, it burns without any residue. It is distinguished from the uric-acid concretion by its insolubility in carbonate of potash, and also by its dissolving in nitric acid with a yellow colour, which does not change to red by evaporation.

Cystinous Calculi.—Calculi of cystine are less rare than the foregoing. Frequently they are found almost pure, or containing but insignificant traces of foreign matters; they are generally rather small, rounded, and possess a yellow colour. Their surface is smooth, and presents a shining and crystalline aspect. They are distinguished from the preceding calculi by their solubility in weak acids. If a portion be dissolved in ammonia, and the solution left to evaporate, the cystine is deposited in crystals which, under the microscope, present the form of flat, six-sided prisms.

Phosphatic Calculi.—Urinary calculi are but very rarely constituted of pure phosphate of lime. Wollaston scarcely ever met with any such. When, however, we do find them, their surface is smooth and brownish-coloured; and they are formed of concentric layers, which separate with the greatest facility. They have a radiated fracture, apparently formed by parallel fibres. The nucleus of the bladder serves as their cement; when heated, they turn black, giving out a smell of horn; this carbonaceous mass burns, and even fuses at an elevated temperature. Where, however, this phenomenon occurs, we must satisfy ourselves that the calculi contained no phosphate of magnesia. They are, moreover, dissolved by acids.

The double phosphate of ammonia and magnesia is never met with in a pure state in urinary calculi; but it often forms the greater part of them. These calculi are almost always white; their surface is rough, and furnished with small shining projections. Their structure is never lamellar, and they are very pulverizable. In some rare cases they are hard, and have a crystalline fracture. The acids dissolve them, while the alkalis precipitate these solutions, at the same time regenerating the original salt. Caustic potash liberates their ammonia. When heated in a platinum capsule, they turn black, at first giving out their ammonia, and eventually they melt, forming an enamel-like substance, or a red-coloured globule, should a little nitrate of cobalt have been added before their fusion.

Fusible Calculi.—The calculi most frequently met with, next to those of uric acid, are formed of a mixture of phosphate of lime and ammoniaco-magnesian phosphate. They are ordinarily rounded, or slightly elongated. Their surface is often smooth, rarely crystalline, and is either of a white, grey, or pale yellow colour. Their fracture is somewhat compact, never lamellar; it often presents small cavities lined with shining crystals of the ammoniaco-magnesian phosphate. They sometimes acquire a very considerable magnitude, but their density is in general less than that of the other calculi. Heated on a platinum plate, they blacken, and at the same time disengage ammonia. At an elevated temperature, they become fused; their fusibility, however, diminishes in proportion as the quantity of phosphate of lime which they contain is increased. A great excess of the magnesian salt, in like manner, renders them less fusible.

When acted on by dilute acetic acid, the ammoniaco-magnesian phosphate is dissolved, and may be precipitated by ammonia. On the contrary, the greater part of the phosphate of lime remains in the residue, which is entirely soluble in hydrochloric acid; if ammonia be

added to this solution, so as to neutralize it as nearly as possible, and we then treat it by a little oxalate of ammonia, we shall have the lime precipitated in the state of an oxalate.

The liquor, being filtered and supersaturated with ammonia, gives with chloride of magnesium a precipitate containing phosphoric acid, recombined under the form of an ammoniaco-magnesian phosphate.

Carbonated Calculi.—Calculi exclusively formed of carbonate of lime are very rare, and are chiefly met with among the herbivorous animals. They are white or grey, sometimes yellow, and even brown or red. Their colouration is owing to the presence of a little animal matter, which becomes carbonized by the action of fire. They are easily recognisable by the property which they possess of effervescing with acids, and, further, by their leaving a residue of caustic lime when strongly calcined.

Most frequently it happens that the carbonate of lime is found mixed with the more ordinary materials of calculi. We have sometimes seen old calculi of earthy phosphates covered over with a thin layer of carbonate of lime. Proust has met with a calculus the outer surface of which was formed by a mixture of oxalate and of carbonate of lime, the next layer by phosphate and carbonate of lime, and the third by simple phosphate of lime. Brugnatelli states that he has found a calculus of carbonate and oxalate of lime, mixed with benzoate of ammonia; this latter salt being soluble in water, it is difficult to explain how it could have become deposited in the urine.

Carbonate of magnesia is rarely met with in great quantity in calculi of carbonate of lime. M. Berzélius, however, affirms that it always exists there, and he cites an analysis of M. Lindbergson, who found in one of these concretions 62.55 per cent. of carbonate of magnesia.

Mulberry Calculus.—Among the more common calculi, we must also cite those which are formed of oxalate of lime. Their surface is commonly rough, and covered with little nipple-like projections or asperities, which give them a very peculiar form, similar to that of the mulberry. Hence, the name of mulberry calculus. The size of these concretions varies from that of a hemp-seed up to a pigeon's egg. They present, especially when of large size, a brown colour, sometimes even approaching to black. This colouration is attributable to the colouring matter of the blood which, from the irritation caused by the asperities of these calculi, is constantly escaping into the bladder. In fact, hæmaturia is frequently dependent on the presence of this form of calculus alone. Their fracture is ordinarily compact and granular. Sometimes, according to M. Berzélius, it presents an agglomeration of crystals. Their density is considerable. They ordinarily contain a very large quantity of organic matter. Heated in a platinum capsule, they swell up and become carbonized; after incineration, there remains a residue of caustic lime, provided the temperature has been sufficiently elevated. Hydrochloric acid dissolves them—a circumstance which distinguishes them from uric-acid calculi; the alkaline carbonates equally attack them, and transform them into carbonate of lime. According to some authors, it would appear that children are especially subject to this species of calculus.

Fibrous Calculi.—Dr. Marcet has described a calculus of very remarkable composition. It contained a matter insoluble in water, alcohol, and ether, but soluble in potash and in boiling acetic acid; prussiate of potash precipitated it from this solution. Marcet regarded this substance as identical with fibrine. It had, moreover, the appearance and consistence of yellow wax, and was up to a certain point elastic.

Silicious Calculi.—Fourcroy and Vauquelin found some silica in two calculi which they met with; the first contained but a very little, whilst the second was formed by a nucleus holding 66 per cent. of silica, and 34 per cent. of animal matter. They also discovered silica in the gravel voided by a woman.

M. Bousingault analysed a calculus of extraordinary composition; it weighed 17 grains. Its form was irregular; in some parts it was lamellar; it had been passed by a female, and contained—

Peroxide of iron	38.8
Alumina.....	23.0
Silica.....	17.3
Lime	8.0
Water	10.9

The total absence of organic matter in this calculus is extraordinary; and the analogy of its composition with that of some iron mineral bodies, induced a supposition that it had been accidentally introduced into the bladder.

Such is the composition of the different calculi met with in man. They may be classified either as simple or compound, according as they contain one or more of the materials which we have enumerated above. The compound calculi may be mixed or alternating, that is to say, formed by a homogeneous mixture of several principles, or by alternate stratifications or layers of varying composition.

As to their comparative frequency, out of 1000 cases, there were found—

- 372 calculi formed of uric acid alone, or mixed with a small quantity of urate of ammonia, and oxalate or phosphate of lime.
- 253 formed of the earthy phosphates (fusible calculi).
- 233 formed by alternate layers of uric acid, oxalate of lime, and the earthy phosphates; and
- 142 formed of oxalate of lime alone.

THE CAUSES OF SUDDEN DEATH.

By MALCOLM HILLES, Esq.

(Continued from p. 96.)

PART III.

CASES OF SUDDEN DEATH, THE RESULT OF ARREST OF THE RESPIRATORY FUNCTION, CAUSED BY DIRECT VIOLENCE, INJURY, OR ACCIDENT.

It would be foreign to the object of the present papers—and most unprofitable, to consider in detail the various cases of sudden death produced by arrest of the respiratory function, induced by violence, whether accidental or otherwise. It will be sufficient to state, that such accidents may prove suddenly fatal, by inflicting a mechanical injury on the respiratory organs—thereby rendering them incapable of performing the function of respiration, or by destroying the influence of the nerves of respiration.

Severe injuries to the parietes of the thorax—extensive or penetrating wounds of the lungs, in which these organs or the cavities of the chest are filled with blood, afford examples of fatal mechanical injuries to the respiratory organs.

Accidents to the spine or spinal marrow present instances of the destruction of the influence of the respiratory nerves. These induce sudden death, by causing an arrest of the respiratory function, although the organs of respiration have escaped direct injury. Cases of falls from a height, in which the individual pitches so as to fracture or displace one of the vertebrae, or cause a laceration or compression of the spinal marrow, are usually productive of sudden death in this way.

When the part injured is below the level of the fifth cervical vertebra, the individual generally survives a few hours (a) or days; but when the injury occurs at or above this point, death is usually instantaneous. In the former cases the nerves of respiration are not paralysed; in the latter, that influence of these nerves is cut off, and thus respiration is arrested, and death produced.

(a) The victorious Nelson died from an injury of this nature.

It is an interesting provision of Nature, that the respiratory nerves should arise nearly together, from a portion of the spinal marrow situated so high up and so far from the organs which they supply. Thus, for instance, the *phrenic*, which supply the diaphragm; the inferior external respiratory, supplying the serrati magni; and spinal accessory, which are destined to the trapezii muscles, arise from nearly the same point of the spinal marrow, opposite about the fourth cervical vertebra.

If we reflect for a moment, we shall see the advantages gained by this arrangement to be—1, greater security to the individual; and 2, a combination of action which is necessary to produce the mechanical act of respiration. I may be allowed to observe, that the opinion so generally entertained that the phrenic nerves are sufficient to sustain respiration, is not correct; unless the diaphragm be antagonized by the action of the serrati magni, supported by the trapezii muscles, the result will be, when the diaphragm contracts, a drawing in of the lower margin of the thorax, tending to expiration, rather than to inspiration: the ribs, however, having been previously fixed by the serrati magni muscles, the contraction of the diaphragm produces its descent, and the consequent enlargement of the capacity of the thorax, whereby inspiration is performed and maintained.

Death, in these cases, is to be attributed to the arrest of the function of respiration, in consequence of paralysis of the respiratory muscles. In some cases, however, the great shock to the system will also contribute to the fatal result. Under the present head may be considered those remarkable cases of suffocation and sudden death which so frequently occur from a morsel of food or other foreign body stopping in the neighbourhood of the air passages, and most frequently in the pharynx.

I use the term remarkable, because, although these cases are of constant occurrence and are most easily remedied, the profession, generally, are not sufficiently aware of their nature, and many persons thus perish without any help being administered to them, or without, at least, the proper means being resorted to.

The situations where foreign bodies most frequently lodge, so as to be productive of fatal consequences, are the pharynx, the larynx, and trachea. Of these, the pharynx is the most exposed to the stoppage of foreign bodies, in consequence of its contracting, suddenly, towards its termination in the œsophagus, and of its being so frequently engaged in the passage of the food and other substances into the cavity of the stomach.

As this sudden contraction of the pharynx in the œsophagus occurs directly behind and opposite to the lower extremity of the larynx, where the laryngeal constrictor muscles are situated, it follows that so soon as a morsel of food, such as a portion of hard meat, potato, &c., stops at this point, these muscles are thrown into a state of spasmodic contraction, and the consequences are even more rapidly fatal than if the foreign body had entered the larynx itself.

It is, indeed, remarkable that foreign bodies, entering the larynx and trachea, are productive of less immediately serious results than where these have stopped in the pharynx. When an accident of this kind occurs, the patient is usually attacked with severe fits of coughing; in one of these the foreign body is thrown against the rima glottidis, so as to prevent the egress of the air; it here produces alarming symptoms, sometimes partial insensibility; when the patient suddenly inspires, the foreign body descends into one of the bronchial tubes, where it generally becomes impacted, at least for some time.

A case of this nature occurred sometime since in the person of an eminent engineer, and attracted much public attention; several similar cases have been recorded in almost every medical periodical during the last fifty years.

The fatal result, which ensues so rapidly in cases where a foreign body has become impacted in the pharynx, is owing to these sudden spasmodic

action of the constrictor muscles of the larynx, which is induced by the foreign body irritating sympathetic cells, as the nervous filaments distributed to these muscles.

In these cases asphyxia takes place very rapidly; the patient becomes apparently insensible in less than one minute from the occurrence of the accident; the period, however, appears shorter than it is in reality, as the patient is usually struggling for some time unnoticed, and often commands attention only when he falls from his chair in a state of insensibility. Life—that is, organic life—continues in these cases much longer than in those we have described in the preceding section, there being almost always time to send for assistance, and for this to arrive, if at no great distance, before actual death takes place.

This form of death arises purely from arrest of the function of respiration, and is therefore interesting, as affording an example of the mode in which death takes place, from this cause alone. It properly forms one of that division of sudden deaths generally adopted by authors, and first chosen by Bichat, namely, death commencing in the lungs.

Here there is no injurious impression made on any other part of the system: the air is simply prevented from entering the lungs; the blood ceases to be arterialized; venous or black blood circulates through the arteries of the body, enters those of the brain and nerves; the nervous system becomes paralyzed; the respiratory nerves cease to excite the muscles of respiration, this function is still further interrupted; and finally ceases. As the heart continues to contract after respiration has ceased, the left cavity of this organ becomes emptied of its blood, whilst the right cavities and the lungs, as well as the whole venous system, become filled with the fluid. The order in which the important functions of life cease is:—1, respiration; 2 (b), nervous influence; 3, circulation.

Having now considered the prevailing and most important causes of sudden death referable to the arrest of the function of respiration, one of the great vital functions, so essential to the maintenance of life, it may be asked, to what good does the inquiry tend? what beneficial results may be expected from it? how is human life to be preserved, or human suffering alleviated, by such investigation?

Although I have but little respect for the *cui bono* philosophy of the present age, and believe that a single spark elicited from the lamp of truth may lead to the most extensive and satisfactory results, as the distant ray of light seen through the narrow chink leads to a world of light and beauty, I shall not avail myself of any speculative good that may or may not arise from our present subject, but shall proceed to point out how far the theories advanced should prove beneficial.

As the full consideration of this part of our subject would lead us to the treatment of most of the affections that have been alluded to, and thus out of the course originally proposed, I shall only offer a few brief observations in connection therewith, and such as bear directly on the points discussed.

Indeed, I consider any lengthened observations on this head are quite unnecessary at present, as our great object should be, first, to establish correct physiological and pathological theories regarding the phenomena attendant upon life and death; this once accomplished, the treatment will suggest itself without much

(b) In considering the destruction or death of the nervous influence, it should be recollected that the nerves of organic life—or the sympathetic system, retain their power in general to a later period than those of animal life or of the cerebro-spinal system. I do not consider it necessary, however, to dwell particularly on this fact, as a too nice distinction might tend rather to confuse than to explain the subject treated of at present.

difficulty or research. The correct diagnosis of disease is usually more difficult than the treatment.

In the treatment, then, of the various diseases and affections to which mankind are subject, our special attention should be directed to the vital function most seriously impaired or injured: if it be the respiratory, our remedial measures should be applied to the relief of the organs necessary to its maintenance; and so, also, as regards the two remaining vital functions, namely, the nervous and the circulatory. In some cases these measures will be necessarily directed to the relief of a local affection, in others, to the alleviation of symptoms which indicate that the function is generally impaired.

At the same time, it will be borne in mind, that a purely local affection scarcely exists, and that all parts of the animal economy are so intimately connected, at least in man, the perfection of organisation, that no one part can suffer, without the rest sharing in the distress. If this be true as regards the minor or less important portions of the frame, how much more certain is it as respects the great centres of life, the vital functions. Man must be viewed, even when labouring under disease, as a whole, the integrity of which depends on the well-being of the parts, and not as an assemblage of atoms, one or more of which may be disorganized in the general mass without compromising its safety.

It is, indeed, this intimate connection and mutual dependence which exists between the various functions of life that render the diagnosis of disease so difficult in some cases. When speaking of asthma, I related a case of enlarged liver that had been regarded as one of this disease, although no abnormal condition of the lungs existed. The disease here was purely functional, so far as regards the lungs. Similar cases occur to most practitioners of medicine.

How necessary, then, is a correct diagnosis! How indispensable to fix in our minds, if it be possible, the organ affected, which is pathologically diseased, so that we may remove its disordered action, if such be in our power, and so relieve the vital function most seriously disturbed! Our treatment, then, would be based on fixed and certain principles, and the absurd practice, too prevalent in the profession, of prescribing a distinct remedy for each particular symptom, discarded; our attention would be directed to the removal of cause, and not solely to the alleviation of effects, which are frequently uncertain, and may depend on other and sometimes most deceptive causes.

The theoretical views I have advanced regarding the influence which the temperature of the water exerts, in cases of drowning, have been long since anticipated in practice by the officers of the Royal Humane Society, who make use of the warm bath most extensively and most beneficially in cases of suspended animation from drowning. I am not aware that they entertain the opinion, that the morbid impression made by the cold water on the nerves of the cutaneous surface is destructive of life, further than as this fluid acts as a destroyer of the animal heat of the body, and thus tends to a fatal result. The distinction is of no practical importance, as appears to me at present.

If the rapidly fatal action of carbonic acid gas be, as I consider, in like manner exerted on the sentient extremities of the nerves of the bronchial membrane lining the air-cells, how are we to remedy this? How antagonize the baneful influence exerted by it? How convey our means of relief to the parts affected? Can we negative, or destroy the paralyzing effects thus produced by its contact, by exciting other portions of the nervous system, either the cerebro-spinal or sympathetic? Will electricity or other powerful nervous stimulants be of any service?

To these questions I can give no satisfactory reply at present; the field is still open to theory, and, alas! to practice also, as our efforts in these cases are rarely successful. On no subject are we, perhaps, less informed than on the action of morbid poisons on the human subject,—and on

animal life in general. On no subject, therefore, do we more require to be informed.

How much is still before us to be investigated! How much remains yet for us to learn! Let no man halt, then, in the pursuit of knowledge—or dissuade another from the task. The spark that falls from the struck flint is but trifling, yet to what extent may it not be spread by diligence and attention; how easily is it extinguished!

I am sure it is quite unnecessary to offer any remarks as to the treatment to be pursued in cases of foreign bodies becoming impacted in the pharynx or entering the larynx.

We shall next proceed to consider the causes of sudden death in connection with the vascular or circulatory system.

ON SOME POINTS CONNECTED WITH DIABETES.

By M. BOUCHARDAT.

Translated for the MEDICAL TIMES by ALFRED MARK-WICK, Esq., Surgeon to the Western German Dispensary, and formerly Externe to the Veneral Hospital, Paris, &c.

(Continued from p. 35.)

The cases I am going to relate I shall divide into three series. In the first I shall comprehend those that have terminated fatally; in the second, those that have been benefited; and in the third, those that have been cured (a).

FIRST SERIES.

M. B., jeweller, aged forty-eight, was seized almost suddenly with an ardent thirst, and frequent desire to make water. Dr. Requin immediately recognised diabetes, and sent me the urine passed in the twenty-four hours. It amounted to rather more than $7\frac{1}{2}$ quarts, and contained 98 grammes of glucose per quart. The patient had taken during the twenty-four hours about 650 grammes of feculent food.

M. B.'s strength had not become much diminished, and he was tolerably stout. He attributed his disease to the suppression of hemorrhoids. M. Requin prescribed abstinence from feculent food, and the regimen I have already alluded to (b), and at the same time ordered leeches to be applied to the anus. Under this treatment the desire to make water and the thirst immediately disappeared. At the expiration of eight days I again examined the urine: it contained all the principles of healthy urine, but not a trace of glucose, although the patient took daily with his food nearly 200 grammes of feculents. It must not be forgotten that the disease had been recognised and treated from the commencement.

Four years were passed in this way very comfortably; but M. B., fancying himself cured, returned by degrees to the use of feculents in large quantities. The thirst gradually returned, and before he again applied to M. Requin his disease had become greatly increased in severity. I again analysed the urine, of which the patient passed about 60 litres, and found it now to contain 101 grammes per litre of glucose. During this analysis, and before any fresh treatment could be adopted, the patient was suddenly carried off by pulmonary apoplexy.

G., aged forty-seven, cook, does not know positively when the disease commenced, but has complained for some time past of great thirst; and has, during the last twelve months, fallen away very considerably. When he entered the hospital, auscultation caused the existence of a few tubercles at the summit of the left lung to be suspected. His appetite was great, and his thirst excessive. His urine, previous to his diet being changed, amounted to five quarts in the twenty-four hours; and contained, per quart, 104 grammes of glucose. The patient had taken during this period, 550 grammes of feculent food. The feculent food was reduced to 120 grammes per day. At the end of three days, he

(a) [I shall not give the whole of those published by M. Bouchardat, but merely a few of the most interesting in each series.—TRANS.]

(b) See pp. 34, 35.

passed in the twenty-four hours only 2.1 litres of urine, containing 70 grammes of saccharine matter per litre. G. remained in the Hôtel Dieu twelve months, but he never entirely abstained from feculents; and his urine, which was frequently examined, always contained glucose. Several remedies were successively tried, with a view to check the glucosic transformation; common salt in large doses was persevered in for some time, and under its influence the proportion of glucose diminished in the urine; but this amelioration was only transient; bicarbonate of soda was employed in doses of 15 grammes daily, but without effecting any improvement. Creosote was also administered, but without any success. G. procured feculent food by stealth; the sugar contained in his urine increased, and the winter setting in, in the meanwhile, the tubercular affection became accelerated in its progress, and eventually carried off the patient.

Mrs. H., aged thirty-five, a widow. Her husband died about two years since of phthisis, and, what is very remarkable, Mrs. H. assures me that his disease commenced exactly like hers, by great thirst and an enormous appetite. Be it said, however, I have no positive proof of this concomitance. Mrs. H. is considerably reduced, her strength is gone, her skin and mouth dry, her appetite great, and her thirst ardent; she has some difficulty in breathing, and percussion and auscultation prove that there is only a slight congestion towards the summit of the lungs. I advised her to enter the Hôtel Dieu, which she did.

At first no alteration was made in her diet; she took in the twenty-four hours 400 grammes of feculent food, 250 grammes of boiled meat, 40 centilitres of milk, 24 centilitres of wine, and $3\frac{1}{2}$ litres of common tisane; she passed 5.75 litres of urine, which contained 73.2 grammes of glucose per litre.

The quantity of feculents was reduced to 100 grammes per day, and a suitable and sufficiently abundant diet prescribed, which was continued for six weeks. On the eve of her departure the patient passed only a litre and a half of urine, containing 47 grammes of glucose per litre. Her strength had returned, and she was beginning to regain flesh. Notwithstanding my observations, she left the hospital fancying herself cured, and again had recourse to feculents. In a few days all the symptoms reappeared in their former severity, and three weeks had scarcely elapsed before Mrs. H. was brought back to the Hôtel Dieu, labouring under a very severe attack of pneumonia, of which she died in three days.

The lungs were gorged with black blood, and were full of tubercles.

SECOND SERIES—DIABETICS IMPROVED.

M. P., aged forty-nine, resides in the country. Previous to the commencement of his disease he had unusual strength and activity; but since then, now nine months ago, during the whole of which time the affection has been overlooked, he has become indolent, idle, and unable to perform his duties; his thirst is excessive, his appetite considerable, and his desire for feculents great; his mouth is parched, his saliva acid, and his skin dry, &c.

Before submitting him to any treatment, he was ordered to continue his ordinary diet for twenty-four hours. During this period he took 500 grammes of feculent food, and passed 5.75 litres of urine of specific gravity 1.036, having a notation of +13° in a tube of 303 millimètres, and containing 100.4 grammes of glucose per litre (5th of April).

The treatment already detailed was adopted. By this regimen the quantity of urine became reduced in twenty-four hours to 2.2 litres.

I saw this patient again on the 28th of June. His flesh and strength, and his original energy, had become so completely restored that he fancied himself cured. He now passed only $1\frac{1}{2}$ litre of urine, of natural colour and smell, in the twenty-four hours. Its density was 1.030° examined in a tube of 303 millimètres, it had a power of +4°, and contained 31 grammes of

glucose per litre. M. P. never entirely abstained from stimulants, still his diet was satisfactory; he took daily two quarts at least of good wine, and he was clothed in flannel. The skin regained its functions. The patient also took carbonate of ammonia and theriac.

M. A. is at the head of a large establishment in the country, which requires great activity. He was in the prime of life when the symptoms of diabetes first became manifest. The disease was overlooked for six months, and during this time the patient's flesh and strength disappeared, and with these all his energy. M. A. passed in 24 hours 7.50 litres of urine of specific gravity 1.010, having a power of 13.5 in a tube of 311.5. This urine contained 97.30 grammes per litre of glucose. M. A. eat in the same space of time about 750 grammes of feculent food.

His diet was immediately changed to the one we have already described; although he never entirely abstained from the use of feculents, but always took in the twenty-four hours, save with a few exceptions which I shall presently mention, a quantity varying from 160 to 200 grammes; but all the other hygienic means were very carefully employed, and with the greatest vigilance, such as varied and chosen food; wine of excellent quality, in doses of 1½ to 2 litres for the twenty-four hours; daily exercise, and good flannel clothing; in short, nothing was neglected.

From the commencement of the treatment the quantity of urine was reduced to 2 quarts, and sometimes was as low as 1, and even 0.95 litre.

The proportion of glucose in the urine underwent numerous changes. For instance, it immediately decreased to 68.35 grammes per litre, then to 67.40; the specific gravity remaining 1.010. At the end of a month the urine contained only 34.15 grammes; the density being 1.028. I analysed it again two months afterwards, and found 41.90 grammes; but this proportion soon decreased, for a fresh analysis yielded 31.70 grammes.

Twelve months passed in this way, and the symptoms of the disease almost entirely disappeared. The feculents were increased in quantity; but the thirst returned, and the proportion of glucose in the urine became increased, without, however, any augmentation in the amount of the secretion in the twenty-four hours. The specific gravity reached 1.041, and the proportion of saccharine matter per litre 71.66 grammes.

We now arrived at the period of decrease. On the 17th of October there were only 52.63 grammes, the density being 1.035; on the 14th of November, 34.15 grammes, sp. gr. 1.034; and lastly, on the 15th of December, 5 grammes, and a density of 1.019.

Towards the month of February the thirst increased: on the 9th, a quart of urine contained 61.80 grammes, and the density had returned to 1.040; on the 15th of April, the specific gravity being the same, there were 55.40 grammes; and lastly, on the 28th of September, 61.30 grammes, with a density of 1.039.

M. A.'s health is very satisfactory—he has regained his flesh and strength and his usual energy. In fact, no one will believe in his malady. His urine is normal in quantity; and, to be certain of the existence of disease, it is necessary to have recourse to optical analysis, to prove the presence of saccharine matter.

It is still necessary to state that M. A.'s father was a martyr to the gout, and that he himself, notwithstanding his diabetic affection, had experienced very severe attacks. During the febrile period, the glucose disappeared from the urine; but this, however, was a natural occurrence, inasmuch as during these few days the patient was on low diet. Besides the saccharine matter, the urine contained a large quantity of uric acid; the inside of the urinal being coated with its crystals. It is in these cases that the Vichy waters are particularly useful: I have in vain recommended their administration. The carbonate of ammonia was given from time to time, and, under its influence, the proportion of glucose diminished in the urine.

M. T. is the patient to whom I alluded, when speaking of the extraction of diastase in diabetes, and who furnished me the first opportunity of studying glucosic diastase in a state of perfect purity. His disease commenced about two years ago; and, as I have already stated, he has been twice an inmate of the Hôtel Dieu. When he first entered the hospital, he was excessively emaciated; and, although only forty-four years of age, had no venereal appetite; the least fatigue occasioned pains in the loins and limbs.

Before submitting him to any treatment, he was kept for twenty-four hours on his feculent diet. He took 500 grammes of bread, 250 grammes of boiled meat, 40 centilitres of pea-soup, 40 centilitres of wine, and 6½ litres of tisane; and passed 9.75 litres of urine, containing 71 grammes of glucose per litre.

During his first stay in the hospital, he was treated chiefly on hygienic principles. The quantity of wine did not exceed a litre and a quarter—a quantity which I considered insufficient for this patient, but it could not be increased: for, notwithstanding he was most carefully watched, he always sold some to the adjoining patients. Gluten bread was employed; but the rules of the hospital were such that we were unable to change the diet for a sufficient length of time; nevertheless, as I had succeeded in obtaining for him the situation of Assistant in the kitchen, his ordinary diet was somewhat improved, and he, in consequence, made considerable progress towards recovery, and he regained his flesh and strength; but the smallest quantity of feculents always caused the saccharine matter to reappear in the urine; and I have even detected it after complete abstinence from feculents. But I have no great faith in his assertions, for I fear very much that he exchanged some of his wine for bread. However this may be, the patient, believing himself cured, requested permission to leave the hospital. He worked all the summer in tolerably good health, by abstaining as much as possible from bread, and by taking a pretty large quantity of wine or of brandy and water.

His work having at length ceased, and not being able to procure sufficient wine, he was compelled to return to the use of bread, when the disease again reappeared in all its severity. He returned to the Hôtel Dieu at the commencement of the winter. By continuing his feculent diet, he passed six quarts of urine, containing 68 grammes of glucose per quart. Unfortunately, in consequence of his propensity to trade, he could not return to his duties in the kitchen, therefore his improvement this time was slower and less complete; this, however, must be partly attributed to the severity of the season, for when the weather became warmer his condition improved. He never entirely gave up the use of feculents, and there was consequently always glucose in the urine. He only passed from 2½ to 3 litres in the twenty-four hours, containing from 55 to 75 grammes of glucose. Yet he was only ordered 50 grammes of feculent food, 500 of roast meat, and 1½ litre of wine. But I always suspected his fidelity.

The most varied remedies were uselessly administered in this case: bicarbonate of soda in 20-granule doses, in the twenty-four hours, produced no good result; carbonate of ammonia was rather more efficacious, but did not cause the glucose to disappear from the urine; magnesia and lime-water were of but doubtful benefit; still, from having been kept on a good diet, he left the hospital much improved, although depressed in spirits at the thought that want would contribute greatly to aggravate his malady, and to compel him again to enter the Hôtel Dieu.

19, Langham-place.

(To be continued.)

The editor of the *Lancet* gives as his reason for relinquishing the *Course of Physics*, by Müller, the fact that he had been asked by numerous subscribers not to begin it till January, 1848! The prior publication in the *Pharmaceutical Times* is, of course, not adverted to.

FURTHER OBSERVATIONS ON THE CONDITION OF ASPHYXIA, OR INSSENSIBILITY, INDUCED BY THE INHALATION OF ETHER;

And of the Indications to be fulfilled in the Treatment of the Effects of its Maladministration.

By CHARLES SEARLE, M.D., M.R.C.S.E., of Bath.

In the *Medical Times* of the 19th ult. is a report, made to the Académie de Médecine à Paris, by M. Amussat, of his experiments on animals under the influence of the vapour of ether, in which it is said:—"that, during the condition of insensibility induced by the ethereal inhalation, the blood in the arteries was found to be of the venous character, and resumed its florid appearance when the state of unconsciousness had ceased. And that, in animals which had died during the inhalation, the blood was found of the same venous colour in the heart, veins, and arteries." If such are the results of M. Amussat's experiments, they establish, beyond doubt, the correctness of my views on the subject, published in the *Medical Times*, under date of January 5, to the effect that the condition of the patient under the influence of the ethereal vapour is that of asphyxia; and that the sedative or narcotic effects of ether as ordinarily administered is of the same character. Its stimulant operation when so administered, that is, by the stomach, I must, however, first explain, or the views I entertain of its inhalation will not be rightly apprehended. To make this understood, it is necessary for me first to observe that life, the attributes of which are heat and motion, is the result of the chemical action developed in the animal system by the agency of the oxygen of the air inspired in its combination with the hydro-carbonaceous constituents of the food existing in the blood—caloric and electricity, the actuating stimuli of all vital phenomena, being evolved in the process. And as this process of chemical combination and electrical evolution, we may justly infer, takes place more particularly in the capillary or hair-like vessels, wherein the particles of the blood are brought into the closest approximation, and in which the final changes in its composition in relation, at least, to the conversion of arterial into venous blood takes place, hence the excitement of these vessels and motion of the blood in the capillary vessels, or organic life of animals: capillary action being the first visible motion to be discerned in the egg in the process of incubation, and the last to be discovered in animals when death takes place. These views I submitted to the profession as long back as 1830, when I had the honour of reading to the Westminster Medical Society a paper on the subject, and have since enlarged upon in a work recently published, entitled "*The Philosophy of Life, Health, and Disease*."

Now, the transitory stimulating effects of ether, when received into the blood from the stomach, is in virtue of its composition, it being a compound of carbon and hydrogen; its absolute composition is carbon, hydrogen, and oxygen; but the latter, it is presumed, exists in combination with its equivalent of hydrogen in the character of water—that it virtually is, as I say, a hydro-carbon. This, then, we may fairly presume, from its highly inflammable nature, must exist in a looser state of combination, or a condition of greater affinity for oxygen, than that of the fatty or other hydro-carbonaceous constituents of the blood, and would, therefore, when received into the general circulation from the stomach, by predilection of affinity, enter immediately into combination with the oxygen of the blood, and a more active combustion, and, by consequence, excitement of the capillaries of the general system, would ensue; and thus the stimulating qualities of ether, in common with other hydro-carbonaceous alcoholic fluids which operate in like manner. And hence Mr. Spalding, the celebrated submarine operator, found that, when he drank alcoholic beverage, he required a greater amount of air being supplied to him during his operations. But the stimulant

qualities of ether are of a very transitory nature; these effects being soon followed by its opposite condition of narcotism; but before I proceed with these, its effects, as ordinarily administered, I must explain that of the insensibility induced by its inhalation.

The offices of respiration are, the exhalation of carbonic acid gas, and the reception into the blood of its equivalent of oxygen. Now, in the ethereal inhalation, as the air of the lungs presented to the blood for absorption is not only diluted with this vapour, but in admixture also with this hydro-carbonaceous compound, the latter, when imbibed from the air-cell in admixture with the air, from its greater affinity for oxygen than the constituents of the blood, immediately seizes upon the oxygen, and, combining therewith, thus de-oxidates the blood in the lungs, whereby the blood, thence returned to the heart for general circulation, is deprived of its vitalizing qualifications; and hence defective capillary excitement of the heart and brain, and of all the functions, and thus the condition of insensibility and asphyxia induced: limited, of course, by the extent and period of the inhalation; but involving, necessarily, caution that it be not carried to too great an extent, considering that it virtually consists in a species of burking!

We may now comprehend the narcotic and sedative influence of ether which so soon succeeds to its use when received into the blood from the stomach. It having, as I have already explained, by its union with the oxygen of the blood in the general circulation, produced a certain amount of excitement, other portions of the ether existing in the blood, in their circulation through the lungs, enter into combination with the oxygen of the air imbibed, and here de-oxidating the blood at the expense of the general system, produce effects, though less in degree, yet analogous in kind, to its inhalation—narcotism; and thus its sedative influence and reducing power. And thus are all the operations of ether, I am of opinion, very satisfactorily accounted for, and established as such, I think I may venture to say, by the experiments adduced of M. Amussat.

Reverting to a former observation, I may be permitted to add, that precisely in character with the operation of ether, in producing both excitement and asphyxia, are the effects of alcohol, though modified in description by the difference that exists between them: alcohol being soluble in water, and mixable with the blood; and ether not so, but much more volatile and combustible. Alcohol is accordingly much more permanently stimulant in its effects, and only asphyxiating when received into the system in a concentrated form, or where the quantity in a more diluted state has been so considerable that the blood in its passage through the lungs has become incapacitated for transmitting oxygen for the purposes of the general system; that is to say, the amount of alcohol present in the vital stream de-oxidates the blood in the lungs before it is returned to the heart for general circulation; and hence the more enduring condition of insensibility which succeeds intoxication, the whole vital stream abounding with its polluting influence.

If the explanation afforded be considered the true one, the circumstances prohibiting its use are obviously those of feeble power, as well as apoplectic predisposition, as the effect of all narcotics and reducing agents on the system is to produce venous congestion; and, from reasons afforded in my work "On the Philosophy of Life," but too lengthily in description to be here adduced, and more especially manifested in the liver and brain; hence there was found, on examination, in the case of death recorded from ethereal inhalation, congestive fulness of the bloodvessels of the brain; and, moreover, that bleeding was found useful in the recovery of dogs which had been rendered apparently dead by its use, as so stated in France. But the most obvious and direct indication to be fulfilled, in a case of its maladministration, is the re-excitement of ca-

pillary action by the inhalation of oxygen gas; subsidiary to this, or when this is not immediately available, judicious blood-letting is the next object, followed by the excitement of the skin, and respiratory function of the lungs, by the sudden splash of cold water, followed by galvanism and artificial respiration in extreme cases. And, as an internal stimulant, ammonia, alcoholic fluids, or agents of the like character, being interdicted, nitric acid might prove more useful in these cases than ammonia. In India I once drank an entire drachm in a tumbler of water, and with, I thought soon after, decided exhilarating effects. In addition to these means, warm salt-water clysters are clearly indicated; and, although the last to be noticed, I am not sure that it is the least in importance, an emetic may prove a useful ancillary.

Bath, March 27.

DISSECTION WOUNDS.

By J. E. PATTISON, Esq., Surgeon, London.

CASE OF SIMPLE PUNCTURED WOUND FOLLOWED BY SYMPTOMS SIMILAR TO THOSE EXPERIENCED IN DISSECTION WOUND.

Amongst the numerous writers who have written on dissection wounds, few of them seem to have observed that punctured wounds, followed by similar symptoms, are not unfrequently seen in general practice; though from the often trifling nature of these wounds, such as the prick from the splinter of deal wood in the present case, the local affection is frequently forgotten or unheeded in the urgency and danger of the more formidable constitutional symptoms.

How is it, inquires Mr. Shaw—(who is an advocate for the influence of a septic agent in causing the disturbance),—how is it, says he, in his paper "On Dissection Wounds," if the symptoms depended merely on the puncture, that we have not those effects, *i. e.*, symptoms of dissection wounds, constantly taking place in common life among artificers? So also do most of the other writers on this subject argue, as though the symptoms following dissection wounds never occur in common life among artisans.

If this were strictly true, then there would be good reason for believing the usual formidable symptoms* to be dependent on the absorption or reception of some septic agent; but, as examples of the same range of symptoms from simple punctured wounds multiply, the doctrine of the inoculation of a morbid poison into the system, as productive of the mischief, must be qualified by the assertion, that the same range of symptoms do occasionally take place from simple punctured wounds, such as carpenters, joiners, and artisans receive while at work; so that, in this controversy of the influence or non-influence of a septic agent, perhaps it will be found that both are right, and both are wrong—that the formidable symptoms may arise from absorption of poison in some cases, whilst in others it may be dependent on the state of the body at the time of the infliction of the injury. I shall relate a case illustrative of this opinion:—Mr. B., a carpenter, called on me at my surgery, on the 8th of December last, complaining of being unwell; he was rather slight made, dark complexion, and was fifty-two years of age; his habits of life were temperate, but he had lately suffered heavy losses from bad debts, which affected him, as he stated, very much, producing despondency and loss of appetite. He said he felt a continued inclination to be sick, and complained of faintness and being chilly, and that he had no mind for work, owing to excessive lowness of spirits. Thinking that something he had eaten might have disagreed with him, I prescribed an emetic, and promised to call and see him in the evening at his residence.

When I saw him at eight p.m., other symptoms had set in; he complained of severe headache; the emetic had acted well, still there was great restlessness and languor, the pulse was frequent and sharp, and the tongue coated; he now complained, too, of pain in the shoulder,

and a stiffness of his right arm. I bled him to sixteen ounces, and, as I was undoing the button at his wrist, I observed a small puncture. A wound just under the nail of the second finger, which, he said, arose from a splinter of deal wood pricking him the day before; on examining this prick (for it could scarce be called a wound), it looked a little red, and had a pustule on it; I directed the patient's attention to it; he said, as it gave him no pain, he had not applied anything to it. I freely lanced the part by making a crucial incision, which bled freely, and ordered a poultice, and prescribed a laxative mixture, with two grains of calomel in a pill, to be taken every four hours with each dose of the mixture.

On the morning of the 9th I again saw the patient, when the symptoms of dissection wound had fairly set in: the pain in the shoulder had increased in severity; the breathing was difficult, attended with quick pulse; great mental depression; dry and brown tongue, which was tremulous, as though he was suffering from delirium tremens; the expression of the countenance was haggard, and the nervous shock threatened an alarming termination. On examining the axilla, I found it puffy and painful; the medicines that had been ordered on the 8th had acted freely on the bowels; and on the evening when I saw the patient, as the fever had assumed an irritative or typhoid kind, I prescribed a diffusive tonic mixture, containing ammonia and camphor, and gave him extract of henbane to procure sleep.

On the 10th, on examining the axilla and chest, the latter of which the patient complained of, as being painful, I perceived a slight erysipelatous redness over the pectoral muscle; the pulse had increased to 120, but weak. During the night he had been at times delirious, and attempted to get out of bed to go to his workshop. At the time I saw him, however, this had passed off. At the wish of the friends of the patient, a physician was called in for consultation, and we agreed to favour the formation of pectoral abscess; so poultices were ordered, and hot fomentations, to the seat of pain in the pectoral muscle. He had continued taking the calomel pills, and his mouth now became slightly affected; the mercurial was discontinued. At night I gave him a full dose of morphia, as the henbane had failed in procuring sleep.

On the 11th day, many of the symptoms had increased in urgency, assuming more and more the typhoid type. Delirium was present more or less during the day, and, as he felt distinct chills, I was in hopes that pectoral abscess was about forming, and ordered the parts to be continually fomented, and the diffusive tonic mixture and anodyne at bedtime to be continued.

On the 12th, on visiting him, I fancied there was matter under the clavicle, formed in the swelling of the pectoral muscle, though I could perceive no distinct fluctuation; I, therefore, made a deep incision with the abscess lancet, and was gratified by the discharge of a quantity of pus, which very much relieved him. From this date the symptoms gradually subsided; the convalescence was, however, slow, though large quantities of quinine and wine were taken in conjunction with a nourishing diet; the arm at length renewed its power of motion as the discharge from the abscess lessened.

On comparing the symptoms in this case with those that arise from a common dissecting wound, the similarity will be seen to be very great: there was present inflammation of a distinct kind perfectly different from erysipelatous inflammation; the fever was of the typhoid type, similar to that induced by the morbid poison from dissection wound; the colour of the skin, too, that covered the pectoral muscle was more of the tint of the purple peach-blossom tinge than the red hue of phlegmonous inflammation. It may also be noticed, that, after the peculiar peach-blossom colour of the inflammation had disappeared, it left no desquamation after it, which is usual and characteristic of erysipelas; and as to the fact observed by Mr. Colles and other writers on this subject, of the incisions producing

no discharge in cases of true swellings from dissection wounds, my own experience of the disease, as a sufferer from the inoculation of the morbid poison, would tend to contradict this opinion, as the incision made in my pectoral abscess was followed by a copious discharge of pus, and its attendant relief. The mental distress so truly appalling in dissection wound was here present from the first, and, with the tremulous tongue, indicated the powerful shock on the nervous system. The presence of delirium and the haggard expression of the features in this case were precisely similar to the same results so generally following the introduction into the system of a septic agent. In this case of recovery, too, as in those from dissection wounds, every portion of the limb between the original wound and the seat of pain in the shoulder and pectoral muscle was swollen; the subsequent pains of a rheumatic character were manifest also in this case: so that, taking the whole range of symptoms and circumstances attending this case, and comparing them with those attendant on dissection wounds, the similarity, to say the least, is very striking, and tends to favour the opinion that, in peculiar states of the system, a simple wound may be productive of similar symptoms to those sometimes following the wounds received in the dissecting-room, or the *post-mortem* examinations of the dead from inflammation of the serous and peritoneal membranes.

NEW MODE OF TREATING UTERINE HEMORRHAGE.

By T. R. TORBOCK, M.D.

I wish now to redeem my promise of furnishing such cases which, in my humble estimation, will fully prove the inestimable advantages of the plan set forth in my former communication, viz.—“The injection of stimulants into the cavity of the uterus by a suitable apparatus, so as to arrest flooding.” Having mentioned my views to one or two of my medical friends, they were not prepared to give an opinion—the novelty of the plan, and the means recommended, being such as, very judiciously, to prevent them giving an opinion *pro* or *con*; however, I was soon enabled, practically, to prove the correctness of my views, by being called in consultation with my friend Mr. F. Thompson, surgeon, of Sunderland, when a frightful hemorrhage followed the extraction of the placenta.

This case was one, of all others, where the application of stimulants might have been dreaded, as superinducing untoward symptoms, and that owing to its peculiarity. The patient, a delicate female, between the age of twenty and thirty years, was seized with labour, when Mr. Thompson, her medical attendant, was summoned to attend. For the first few hours, everything appeared to progress favourably; the second stage being ushered in, it was found that little or no progress was made in the descent of the child, notwithstanding the presentation was natural. A more minute examination was now made, when it was found there existed an impenetrable barrier to its descent—the mouth of the womb being completely closed by bands of adhesion—the result of a former accouchement, which took place at Hull, at which time great violence had been used in the extraction of the child by means of the forceps; moreover, there existed a *recto-vaginal fistula*, which rendered the case still more perplexing and difficult. On my arrival, accompanied by my friend Mr. H. H. Taylor, surgeon, we at once found matters to be as represented by Mr. Thompson, and concluded in consultation that a division of the several bands (anteriorly and posteriorly) should be attempted by means of a curved bistoury; this was speedily effected by Mr. Thompson. Notwithstanding, after waiting a considerable time, and the patient becoming exhausted, it was thought expedient to accomplish the delivery by means of the forceps. This was speedily done, and the placenta extracted. It was at this moment, from the stonic state of

the uterus, frightful hemorrhage followed. The ordinary means were used to produce uterine contraction, as pressure, grasping the uterus, secule, and the introduction of the hand into the uterus. At this critical moment was suggested the introduction of a piece of rag, saturated with brandy diluted one-third with water, into the uterine cavity, which was very promptly done; when on a second application it was grasped by the contracting uterus, all hemorrhage ceased; the patient progressing favourably. The second case was one which occurred in the practice of my friend Mr. H. H. Taylor, the like mode being adopted with the most gratifying results; the stimulant used in this case, if I mistake not, was rum alone.

Kirkby-Stephen, March 10.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF SCIENCES.

Meeting of March 22; M. BRONGNIART in the Chair.

ETHER.

M. Flourens read a short paper on the action of ether on the nervous system. Unconsciousness is produced by that substance only when exhibited by inhalation. M. Flourens gave to dogs from 3jss. to 3vj. of ether internally; they were intoxicated by it, but insensibility was not produced. Having injected ether into the arteries of other animals, M. Flourens had noticed the interesting fact, that motility disappeared before sensibility: a succession of phenomena contrary to that usually observed in the human subject after inhalation.

A letter was also read from Dr. Jackson, in which Dr. Jackson explained that, if he had taken out a patent for his discovery, it was less to protect its commercial value, than to establish his claims to priority of invention. Dr. Jackson had unsuccessfully repeated Dr. Wells's experiments, and could not acknowledge that gentleman's claims to the discovery of the stupifying properties of inhaled ether.

ACADEMY OF MEDICINE.

Meeting of March 23; M. BEGIN in the Chair.

The meeting was entirely occupied by a long paper on ether, by Professor Blandin; we expected this communication would bring forward some new facts, or present the question in a new light. It was not so: the paper contains nothing but what is already known: it comes one day after the fair.

PARISIAN MEDICAL SOCIETY.

Meeting of March 24; Dr. SHRIMPTON in the Chair.

The following case was read by Dr. Olliffe:—
CASE.—UMBILICAL HEMORRHAGE—PUTRUM—
DEATH—DISSECTION.

The case was that of a child in whom, six days after birth, the funis was detached; on the eleventh day of life an oozing was observed from the umbilicus which continued in an alarming manner during several hours. Cauterization with nitrate of silver, twice repeated, had proved unavailing; compression was too painful to be borne, and the application of the ice was unsuccessful, every scream of the child being followed by an increase of the hemorrhage. Professor Dubois saw the case during the night, and the ligature of the umbilicus was resolved upon. The operation succeeded perfectly in arresting the hemorrhagic discharge; but the child remained very small, and in a state of great debility; occasionally a small quantity of putrid blood was passed with the motions. Icterus was present. A homoeopathic practitioner was called in, and that gentleman did not hesitate to promise a complete cure in the space of four days; on the second, however, the child died after a very abundant intestinal hemorrhage.

Sectio Cadaveris, thirty-six hours after Death.—Rigidity complete; icteric colour of the skin; no traces of purpura; cicatrix of the umbilicus complete; skin round the scar healthy.

Abdominal Walls.—The umbilical vein was almost entirely obliterated, contained no blood, and was all but converted into a fibrous chord; the left umbilical artery was obliterated. The right umbilical artery presented a different aspect: its external appearance resembled that of a vein; small eminences were noticed from distance to distance, which, being incised, gave issue to a few drops of blood, and to very minute clots; its cavity readily admitted a probe as far as the umbilicus. The tubercle was divided by a series of horizontal sections, the deepest of which discovered a surface—in appearance fibrous, brilliant, and bluish. On the inferior and right side of the tubercle was a red spot, from which small clots of blood were forced out. It appears therefore certain, that the hemorrhage arose from the right umbilical artery.

Digestive Organs.—The palate and tongue were covered with purpuric spots, already observed during life; the stomach and small intestines were healthy; but the cecum, colon ascendens, and right half of the arch of the colon, presented a uniformly red hue; and on two or three spots were observed submucous hemorrhagic blotches. The liver was large, its colour natural; gall-bladder small and empty; near its neck, externally to the cystic duct, was observed a small tubercle, attached by cellulo-fibrous adhesions to the liver, with the substance of which it was otherwise unconnected; it was equal in size to a pea, and rather less dense than if it were of a fibrous nature. The hepatic vessels healthy. The spleen natural, rather large; peritoneum healthy.

Urinary Organs.—Kidneys natural, with the exception of a small purpuric spot on each; ureters and bladder natural; urachus obliterated.

Respiratory Organs.—No alteration.

Circulation.—Heart small, pale, and soft; foramen ovale incompletely closed; thymus not congested.

Organs of Innervation.—Cerebral substance soft and rather diffuent; extravasated blood in the subarachnoidian cellular tissue, near the pons varolii; a few diffuent clots in the lateral ventricles; anterior fontanella enormous. Spinal chord not examined.

FACULTY OF MEDICINE.

LECTURES ON GENERAL PATHOLOGY, BY
PROFESSOR ANRIAL.

Some diseases, eruptive fevers, for instance, have a predetermined and invariable course, to arrest which art is powerless. Their symptoms may be slightly modified, their intensity diminished, their dangers lessened, but their course and duration remain the same. Other acute affections can, on the contrary, be arrested by the interference of medical art. Such is pneumonia during its first stage.

In general the morbid phenomena of acute disease acquire in the evening a greater degree of violence than during the day; this increased intensity of the symptoms is termed “*exacerbation*”; at this hour not only are the previously existing symptoms more manifest, but those which had ceased may return, or even new symptoms appear. The reason of this change for the worse, generally observed in the evening during the course of acute maladies, is perfectly unknown to us.

We have hitherto treated of continuous affections; but disease does not always present this type: it may be periodical, intermittent, or remittent.

A disease is said to be continuous when its characteristic phenomena follow an uninterrupted course; and we have nothing to add to what we have already said of the progress of affections of this sort.

A periodical malady is one, the symptoms of which return from time to time, without regularity—epilepsy, for instance. The progress of

such affections is very irregular, and is called "erratic."

A disease is termed intermittent when the symptoms reappear at stated intervals: each of the attacks is called a paroxysm (*accies*). The return of the paroxysms may be quotidian, tertian, quartan (every third day): a double-tertian fever is that which occurs every day, the alternate paroxysms being similar to one another. Mensual and annual paroxysms have been also admitted to exist; but it is not well proved that intermittent diseases can present so long an interval as the latter. We find intermittent affections in five of the fourteen classes of diseases we have admitted, viz., in pyrexia, in hyperæmia, fluxes, hemorrhages, and neuroses; but, whatever the nature of the intermittent affections, they are all relieved by one medicine—cinchona.

Intermittent pyrexia are the types of intermittent diseases. Each paroxysm consists of three stages, which are called the cold, the hot, and the sweating stages. Of these three periods, one alone never fails, it is the hot stage: the chill and sudor may fail, or be exaggerated. When the paroxysms are not marked by any important local symptoms, the fever is said to be simple. But when serious local manifestations appear during the fit, and threaten immediate danger, the fever is called pernicious. In general it is the third paroxysm of such fevers which is fatal. The nature and form of these perilous accidents of pernicious fevers vary considerably, often testifying great disturbance of some important function, by delirium, convulsions, paralysis, dyspnoea, diarrhoea, or syncope: from the kind of symptom observed, each variety of pernicious fever derives its name—hence apoplectic, convulsive, comatose, or syncopal fever. Instead of a functional disturbance, it may be the exaggeration of one of the natural phenomena of the paroxysm—rigors, sudor, &c.—which may mark the fit as pernicious. Sometimes it is only the sudden and fatal collapse of all vital power which characterizes the paroxysm and points to its fatal nature. Intermittent fevers may be caused merely by marshy emanations; they are then idiopathic; they may also be symptomatic of other maladies. The urinary organs and the liver seem to enjoy the privilege of expressing their sufferings by creating general intermittent paroxysms; at the same time, let us say that, when once a patient has suffered from idiopathic ague, its symptoms may, at a future day, reappear on very slight provocation.

Hyperæmia are occasionally observed to adopt the intermittent type; they are noticed chiefly on the skin and on some mucous membranes, the conjunctiva for instance; cerebral congestion occasionally presents this form. The existence of genuine intermittent inflammations is, at least, doubtful. Intermittent cutaneous eruptions, such as urticaria (nettle rash), cannot be called inflammations; they belong more properly to the class "congestion."

Intermittent mucous discharges and hemorrhages have been not unfrequently noticed. But intermittent neuroses are very common. Mania occasionally puts on this form; and very frequently neuroses of sensation, specially neuralgia; and amongst the varieties of this genus, cephalia and facial neuralgia.

The shortest description we can give of remittent diseases consists in saying they are continuous diseases, during the progress of which, at almost regular intervals, a chill is observed. The history of their progress may be inferred from what we have already said of the progress of continuous and intermittent affections.

Turning to chronic diseases, we find that, for the most part, they are continuous; they may, however, be also periodical, returning in the shape of more or less distant attacks. Their progress may present remissions, unexpected alternations, and exacerbations.

Chronic maladies, such as scrofula and syphilis, may show themselves by the successive development of various groups of symptoms.

Where chronic disease has invaded any precise seat, independently of the local symptoms, a certain number of general manifestations belonging to chronic affections make their appearance. These general symptoms may be referred to several causes: some depend on the disturbance of the function of the diseased organ. Thus, in cancer of the stomach, an imperfect digestion becomes the cause of an equally imperfect nutrition; others depend on sympathy; others, again, on derangement of the nervous system; a fourth set are produced by the gradual change of composition of the blood; and, lastly, some are due to more or less mechanical impediment to the freedom of circulation. Amongst these morbid phenomena some belong more particularly to the alteration of the functions of nutrition. Thus, in most chronic diseases, digestion is sooner or later impaired, particularly when they are hurrying on to a fatal termination. Sometimes the appetite remains even after hectic fever has set in, but a time surely comes when it is replaced by a disgust for food. Some symptoms furnished by the digestive organs are special to peculiar maladies; thus the diarrhoea of consumptive patients cannot be considered in the light of a complication, it is a symptom belonging to phthisis. General weakness and oppression belong to chronic maladies in general, and are usually proportioned to the diminution which has taken place on the globules of the blood. The circulation is also more or less disturbed; palpitations, for instance, are observed in most cases. As to fever, it is not an inseparable companion of chronic diseases; many neuroses, for instance, are never attended with febrile excitement. But chronic inflammation and accidental products almost invariably occasion fever at one period of their existence: it is when a local process of diminution has set in, and when the consistency of the morbid products is beginning to diminish. This is particularly well-marked in tubercular disease; in cancer it is not very rare to find patients affected with a softened cancer if the stomach or liver still remain free from fever. The history of this form, hectic fever, I will lay before you next winter, when treating of semeiology. We may, however, say at present, that in chronic disease, when feverishness sets in, it consists only of frequency of the pulse; the heat of the skin appears some time later: in general, much anxiety is justified by the mere acceleration of the arterial circulation. The febrile excitement produced by chronic disease may, during the first days of its manifestation, assume a periodical type, it may even closely resemble ague, and further, it is not impossible that it may sometimes yield to the exhibition of cinchona or its preparations; but after a short time quinine ceases to have any influence over it, and may aggravate the internal disease. We must, however, carefully distinguish those other cases in which a chronic disorder becomes complicated with intermittent fever. This intervention may exercise an unfavourable and, occasionally, a favourable influence on the progress of the original complaint: we have seen cases of neurosis, and others of chronic inflammation, cured by this process.

During the course of chronic affections, the secretions are generally more or less modified. The secretion of fat, for instance, is usually suspended. Perspiration is suppressed in some maladies, for instance enteritis, cancer of the stomach, diabetes, &c. Perspiration is, on the contrary, very much increased in others, such as phthisis, internal suppuration, &c. Many patients present a tendency to nocturnal perspiration long before caverns are formed in the lungs, and this sign is usually very useful to assist a doubtful diagnosis. In many chronic disorders, oedema, anasarca, and serous collections are observed; they depend not upon debility, as it was formerly believed, but, as it has been elsewhere established in these lectures, on a change of composition of the blood, or an obstacle to its free circulation. Towards the close of chronic maladies it is not unusual to observe a pulsa-

ceous secretion on the tongue, and on the mucous membrane of the mouth—a most unfavourable prognostic sign. Urine is less changed by chronic than by acute affections. In cirrhosis of the liver, when ascites has appeared, the renal secretion is much diminished in quantity, and contains a large amount of lithate of ammonia. In general, where great weakness is present, and the globules of the blood diminished in number, the urine loses a considerable part of its solid elements.

Chronic disease, is attended with symptoms referrible to the sensitive or animal functions. The intellect seldom preserves its undiminished power. The moral condition of the patient is also worthy of attention; at the beginning of their malady, at a time when their sufferings are doubted, when their disorder is often referred to imagination, patients so labouring under the first attacks of a chronic malady fall into low spirits, and despond. Their internal disease progresses, and in proportion to their rapid advance towards death the patients recover hope. Nothing in this respect can be more striking than the sanguine dreams of consumptive persons, who, during the last hours of their life, form plans for future years. Cancer of the stomach does not, however, present the same features: persons affected with it are usually melancholy. Sensibility is generally altered—it may be increased or perverted; motility becomes less and less active, and its diminution is frequently remarkable at the very beginning of chronic affections—a fact which often adds to the very great difficulty of the diagnosis in young women between chlorosis and incipient consumption. With regard to the function of generation, we find that, in most women, chronic maladies disturb more or less the catamenial excretions, and sometimes suppress them altogether: a remark to be borne in mind, in order not to consider this arrest as a cause of disease, when it is only its natural result.

Some circumstances stop the progress of chronic disorders, or otherwise modify it: *per se*, chronic affections follow an irregular course; we have mentioned their alternations of improvement and exasperation—their occasional diminution of speed, their frequent increase of rapidity. Spontaneously, or by the efforts of art, chronic disease sometimes assumes an acute form, and the fact may exert a favourable influence, as it is often observed in cutaneous disorders. Amongst the circumstances which may considerably modify the progress of chronic disease, let us mention puberty, menstruation, hemorrhoids, and pregnancy.

What we have said of the progress of disease may dispense us with laying any stress upon its situation. We now come to the termination of maladies; disease may terminate—1st, by death; 2nd, by a return to health; 3rd, by transformation into another disorder; 4th, by passing from the acute to the chronic state.

In acute disease, when death occurs, it is always from the disturbance of the action of the brain, heart, or lung, and in most cases it is due to the lung becoming an improper agent of hematosis, in consequence of diminution of the energy of the contractions of the heart, or gradual extinction of cerebral influence. Some individuals, labouring under acute disease, expire suddenly, at a period when they seem still to have preserved considerable strength; others die, as it were, by the gradual exhaustion of vital powers. All this we can readily understand where the function of the affected viscus is one of great importance, such as the lung or brain, for instance; but it is not so easy to account for death where the part occupied by disease does not perform a function absolutely necessary to the continuance of life—the peritoneum, for instance. Here we believe, that, in consequence of the great extent of the membrane, a concentration of vital energy takes place, by which the other parts of the system are dangerously depressed. In chronic disease, death may be the result of the gradual progress of the morbid change, of an intervening inflammation, or again follow some

accident, due to the development of the disease itself, for instance, hemorrhage in cancer, or pneumo-thorax in phthisis; death may also be the first indication of latent disease, as it often happens in aneurism of the aorta. Sometimes, in chronic maladies, life is suddenly terminated by syncope, and no anatomical cause of the fatal issue can be detected on dissection.

The return to health is the second termination of disease—it may be gradual or sudden; in most cases illness is separated from perfect health by a condition called convalescence, which we will study on a future occasion. In febrile or acute maladies the general symptoms always yield before the local.

When disease is on the point of ceasing, certain concomitant symptoms are often observed, to the apparition of which the physician is tempted to refer the cure: they are called critical phenomena, and will occupy our attention at our next lecture.

EXTRACTS FROM THE MEDICAL PERIODICALS.

A MEMOIR ON EXOSTOSIS, BY PROFESSOR ROUX.—In this interesting paper the learned professor treats only of those tumours which, organized like bony structures, arise from the surface of the bone like one of its natural processes. Professor Roux has met with them more frequently in the inferior parts of the femur than elsewhere. The upper part of the humerus is also subject to the same disease, also the inferior maxillary and the phalanges, peculiarly the last phalanx of the great toe. Dupuytren had directed formerly the attention of the profession to the latter, which causes much pain, and recommended to divide the nail—remove it—and with a small saw, or a pair of bone-nippers, to take off the projection. This affection appears peculiar to youth, and generally appears between the ages of twelve and twenty-five. Professor Roux presumes that the increase of size of this form of exostosis ceases with the growth of the bony system. The volume of the tumour is always in proportion with that of the bone itself, and it is attached to the diseased part by a narrow basis, too broad, however, to deserve the name of pedicle. The centre of the exostosis is areolar; its surface consists of a thin layer of compact tissue. A bursa sometimes separates it from the skin, but the growth occasionally presents, with the neighbouring muscles, singularly intimate adhesions. These tumours never become malignant, but they always constitute a deformity, may cause much pain, and interfere more or less with the accomplishment of the functions of the limb. The operation for their removal may be performed, without denuding the tumour, by two lateral incisions parallel to each other, through which a chain-saw or the nippers may be introduced for the purpose of dividing the neck of the exostosis. This operation is seldom followed by any distressing consequences.—*Revue Médico-Chirurgicale.*

Hiccough may be arrested in most cases by pressure over the epigastric region. Professor Rostan, who recommends this very simple process, and asserts its efficiency, employs a special truss for the purpose.—*Idem.*

CASTRATION.—M. Baudens proceeds to this operation in the following manner: An incision proportional in length to the size of the testis having been performed on the inferior and external part of the testis, the chord is divided near the epididymis when healthy—near the inguinal ring when diseased. As to the ligation of the funis or of its isolated arteries, M. Baudens rejects it for two reasons—first, because it may cause unpleasant consequences by the constriction of the nerves of the funis; and, secondly, because it interferes with and prevents immediate union. The chord should be seized with a tendon forceps, and divided between the instrument and testis. One suture is generally sufficient, and the dressing consists merely in applications of ice to the wound.—*Gazette des Hôpitaux.*

D. M'CARTHY, D.M.P.

ERRATUM.—Page 80, col. 2, line 29, for "testis" read "icterus."

PATHOLOGICAL SOCIETY OF DUBLIN.

TUBERCULAR CAVITY IN THE RIGHT LUNG OPENING INTO THE SAC OF THE PERICARDIUM—PERICARDITIS.

Dr. McDowell said that the specimen which he then presented to the society exhibited a mode of termination of thoracic disease which, as far as he could discover, had never been previously described.

The subject of the case was a policeman, named James Kenah, aged twenty-nine, a robust, well-made man, and who had always enjoyed remarkably good health, until about three weeks prior to his admission into the Whitworth Hospital, early in June, 1846. When placed under Dr. McDowell's care, he was complaining of cough and dyspnoea, and his countenance was pale and anxious. Careful examination of the chest at this time failed to detect any amount of organic lesion sufficient to account for these symptoms.

The history he gave of his case was, that three weeks before his admission he had incautiously exposed himself to cold, whilst profusely perspiring, and soon afterwards was seized with a severe stitch in the right side, for which he was bled, and with relief. In a few days, a return of the pain required a repetition of the venesection; profuse perspiration now followed, with deep-seated pain in the chest, and cough attended with expectoration of a dark colour. Five days after admission into the hospital, he was suddenly seized with violent and most acute stabbing pain in the left side of his chest, which lasted for several hours, and was accompanied by very severe dyspnoea. Examination of the chest now gave the following results: The natural respiratory murmur existed over the upper portion of the left lung anteriorly, and over its entire extent posteriorly; but anteriorly from the left nipple downwards to the lowest limits of the left lung, the respiratory sound was inaudible, and from this space was heard distinct metallic tinkling, and "bourdonnement amphorique." To percussion the left side of the chest sounded clear throughout, without being tympanitically so over the space where these abnormal sounds were heard. Nothing morbid was at this time detected in the right side of the chest. The symptoms next observed were that the breath became extremely fetid, the dyspnoea more urgent, the countenance continued pale and expressive of suffering, the voice became faint and hollow, the expectoration copious, purulent, and extremely fetid; he had wasting night-sweats, and his pulse was rapid and feeble. Diarrhoea then set in, and his lower extremities became anæsthetic.

When the examination of his chest was repeated, after a few days' interval, there was still distinct evidence of the existence of a large cavity in the anterior inferior portion of the left side of the chest, containing both air and fluid: for here the splashing of a fluid could be distinguished, along with metallic tinkling produced by each cough or forced inspiration; through these sounds the normal cardiac sounds could be heard, but very faint, and as it were distant. Posteriorly, over the inferior portion of the same side, distinct frotement and fine crepitus existed. There was also crepitating râle over the base of the right lung, audible as well anteriorly as posteriorly; and under the right mamma, over an extremely limited space, there was once heard what seemed to be cavernous respiration.

The difficulty of forming a diagnosis in this case was extreme; although the symptoms in some particulars resembled those of pneumo-thorax, yet it was judged that this could not be the lesion, because the metallic sounds were not heard posteriorly; nor was there displacement of the heart, as would have occurred with effusion into the left pleura; whilst the cavity of the pleura was known not to be obliterated, as the continuance of frotement testified. Finding crepitating râle present in the lower lobes of both lungs, it was supposed that double pneumonia

had existed, which had run into the suppurative stage, and that thus a cavity had resulted in the left lung, sufficiently large to yield the metallic sounds, and accounting for the purulent, fetid character of the expectoration. This conjecture, however, the result proved to be erroneous. The patient rapidly sank, violent delirium set in, and death occurred July 26—the duration of the disease being thirty days. The body, which was but little emaciated, was examined twenty-four hours after death. When the sternum was raised the sac of the pericardium, enormously distended, came immediately into view, completely concealing the left lung; on opening this sac, there were evidences of acute pericarditis having existed: the pericardium contained a great quantity of fluid similar to that which had been expectorated, viz., pus, of thin consistence, and a milky white colour, but inodorous; the serous surfaces were deeply coated with lymph, which was deposited in them in irregularly formed masses. On investigating further, as to the cause of this inflammation, a round, smooth fistulous opening was discovered on the right wall of the pericardium. This opening, which was as large in diameter as a common goose-quill, led through a straight fistulous channel, about an inch in length, into a small tubercular cavity in the right lung, near its anterior thin edge. The bases of both lungs, but especially that of the right, were solidified, or rather splenified, from a twofold cause: first, from the existence of pneumonia; and, secondly, from their being the seat of a deposit of milary tubercles. No tubercles were detected in the apex of either lung. This morbid deposit was observed in their bases only.

Dr. McDowell thought that it was not difficult to conclude what had been the order of occurrence of the morbid changes noticed in this case; he thought it probable, here, that pneumonia, occurring in a strumous habit, gave rise to tuberculous depositions; that a vomica, being then formed near the anterior thin edge of the right lung, produced adhesion between the opposed layers of pleura, and then between the pleura and pericardium, and that a communication, subsequently, was established by the ulcerative process between the cavity in the lung and the sac of the pericardium; hence arose the pericarditis, the purulent secretion from the inflamed serous membrane passing into the cavity in the lung, and giving rise to the copious expectoration observed during life, whilst the escape of air from the pulmonary cavity into the sac of the pericardium, with the fluid then secreted, accounted for the production of the metallic sounds. Dr. McDowell remarked that no case similar to this had occurred in the extensive experience of Dr. Stokes, nor was it to be met with in the works of Andral or of Louis. Dr. Graves, in his "Clinical Medicine," has recorded an interesting case where an hepatic abscess opened through the diaphragm into the cavity of the pericardium; but here the physical signs of pericarditis revealed the lesion which had taken place; whereas, in the case which Dr. McDowell had submitted to the society, no such signs existed to throw light on the nature of the case.

TO CORRESPONDENTS.

THE MEDICAL TIMES may be procured by an order on any Newsmen or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed Messrs. Angerstein Curran, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 13s.; Quarterly, 6s. 6d.

A HANDSOME PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 5s. An allowance is made to the trade.

Communications and letters acknowledged.—*Mr. Noble, Bristol; Dr. Palmer, Birmingham; Mr. Roubottom, Brighouse; Mr. Spence Manchester; Dr. Alcock, New Ross; Dr. Flynn, Clonmel; Dr. Stead, Southampton; Mr. Hearne, Gloucester; Mr. Earnshaw, Manchester; Mr. Robinson, Bishops Auckland; Mr. Sherwood, Warrington; Mr. Pugh, Couper; Dr. Davis, Outorards Dispensary; Dr. Jeffreys, Liverpool.*

A.B.—The usual fee used to be a guinea a mile. In making a charge of only seven shillings a mile, a discount has been allowed as large as the profession would be disposed to sanction. There is no authority to which we can refer A. B.; and unless, to whom the matter must be left even by the judges, would decide very arbitrarily and very capriciously.

A Subscriber.—As a surgeon, yes; as an apothecary, no.

Agricola will find his question answered in the Pharmaceutical Times.

A Student.—Dr. Knox's lectures will be commenced on an early day, and continued, without stoppage, to the conclusion.

The case of amaurosis from Liverpool, and some other contributions, are declined.

The letter on the abuses of Guy's Hospital should have been authenticated.

Pos Vaguna's strictures on the College of Surgeons and their examinations are well deserved, but not new.

We cannot decide wagers on the probable duration of the Apothecaries' Company.

Dr. Torbark's case of fracture was received.

Anxiety is mistaken in supposing that we have expressed the opinion that surgeons cannot recover at law for their surgical attendance. There is no doubt they can. They cannot recover for medical attendance.

M. B. H. is thanked for his obliging communication; but it is on a subject we have no wish to discuss more fully.

Mr. Clatter. We do not know any gentleman suited to the proposed task.

Mr. Dutton's letter on the Bakenhead case throws no new light on the matter.

We are much obliged by the civil letter of Miles.

Early in the month will be commenced in the Medical Times, and continued uninterruptedly,

A COURSE OF LECTURES ON SURGERY, BY PROFESSOR SAMUEL COOPER, F.R.S., Professor of Surgery in University College, &c., &c.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the SCIENCE of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our student life; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract love of a pedantic and inapplicable lore. Every power of his mind is engaged: he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate, to be EXERCISED: each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diplomas or licences.

Six of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will

be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is *bona fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, APRIL 3, 1847.

THE LATE INQUEST AT GRANTHAM.

OUR account of the inquest at Grantham, given last week, was headed "Fatal Effects of Ether"—a characteristic blunder, for the mistake of the commencement is faithfully continued to the end of the chapter. So disastrous is it to stumble on the threshold.

What are the real facts of Mr. Parkinson's case? and first, what are they as regards the ether?

The ether was judiciously tried before the operation, to ascertain whether it would affect her, and in what way. The first time it made her laugh very much, and, whilst under its influence, she was pinched very severely; and, when she recovered from its influence, she said she felt quite comfortable, and retained all her consciousness of mind, but had no feeling; she was aware she was being pinched, although she said it did not give her pain. The operation lasted about ten minutes, but the influence persisted about two hours and a half, during which time she was hysterical. On the following Monday evening she was again subjected to the vapour, when its influence was much more rapid, and she became quite unconscious in about four or five minutes. She remained so for about a quarter of an hour or twenty minutes, when she became conscious: *the effect of the ether did not cease for about an hour.* On her recovery she said, "She knew all that had passed in the room, though she was apparently unconscious; she could hear, though she could not see." She was not hysterical the second time. In these cases the other had some effect, although an imperfect one; the patient did not feel pain when pinched, &c. Consciousness was not, however, suspended, although we had insensibility to pain; and no doubt deceased under both these experiments, was in a state—we will not say fit for the operation, for the after effects were equivocal—but in which she would have had no sensation of pain.

The second phase of this question, and which overturns all the talk about "the fatal effects of ether," must now be stated: *the woman was not under the effects of ether at any time during the operation.* The ether was used, but it had failed. This is the answer to the assertion that she died from it. Mrs. Parkinson was "reduced to a state of unconsciousness," says one witness; and in the next breath it is added—"upon every incision made during the operation she moaned and appeared to feel it, as she struggled

and nipped witness's hand." There is no wonder "she felt no pain when the different vessels were being tied up," because that process produces no pain when the ether is not used. This witness, on asking deceased whether she felt any pain during the operation, was answered—"she did when they cut, but not otherwise." To be under the effects of ether, and to be "hurt whenever they cut," and when being "hurt" to "moan, struggle, and nip witness's hand," are, practically, contradictions. Nay, Mr. Shipman, one of the surgeons, gives us his authority that "the deceased felt as much pain as if she had not inhaled the vapour, as she cried out and struggled at each cut." Here was an effect of ether! The poor woman was conscious during the two days and five hours intervening between the operation and her death: here again the narcotic effect of ether! Yet two highly respectable surgeons succeeded in overlooking these facts, and tell the public—the responsibility belongs not to us, but the ether! Was there some mistake in the use of the ether tube? We have heard much of its fascinations and its oblivious agency. Did the medical men take it by mistake for the patient?

The tumour was malignant and must have become fatal; removed, she had a pretty fair chance of life. The operation, therefore, we justify—and likewise its manner. It seems to have been skilfully performed. Thirty-five minutes may, under some circumstances, be fairly spent by a good operator in the removal of a malignant tumour, for its attachments may prove extensive and intricate, and every particle must be removed, or we do worse than nothing. The malignant tumour of course, however, impaired health: it could not exist in a part *not likely to affect the patient's general health.* Deceased, therefore, suffered constitutionally during the fifteen months of the existence of the tumour. One of the surgeons admits she was "delicate." She was, in other words, not in the best state for an operation, although that operation was necessary, and, the ether failing, she had to hear the horror of thirty-five minutes' torture. We are prepared, before hand, to say it is a problem, whether the nervous system can bear the shock apart from all influence of ether: the event proved that it could not. She died of the nervous depression resulting from a necessary operation performed with due skill; another proof of a too well-known surgical principle, that people will sometimes die, do what we may. Happy indeed will be the revolution in the healing art, when incisions six inches long, and vivisections of thirty-five minutes' duration, can be performed on a delicate subject without entailing at times the penalty of death!

The exhaustion noticed in this case is rarely felt where the ethereal inhalation is really successful; and there can be no doubt the deceased, so far from dying of ether, would have had a better chance of life had she been insensible, through its influence, to the pain of the operation. As no blood appears to have been lost, this exhaustion must be taken to result chiefly from pain, and in no small degree from mental emotion, especially from fear: a slight illustration of which every one must have had in the imper-

fect nausea and depression produced by any momentary agony. The nervous depression following the operation is spoken to by one of the surgeons, for he "attempted to produce reaction by the exhibition of ammonia and other applications without success." And the *treatment* points to this state in another part of the evidence. "Mr. Robbs desired that she should be kept quite still." This was very proper treatment for nervous depression after an operation, and proves that at the bedside of his patient the medical attendant was equal to his duties. But, at the same time, it was not the treatment for a person dying of the stupor produced by a narcotic.

It seems, too, that during and after the operation, the patient was perfectly sensible; that after the operation "she spoke in a very low tone of voice, and did not appear to rally" from that time. "She did not rally after the operation." Is anybody surprised at that, or dubious that this was the cause of her death? Under ordinary circumstances, the surgeons in attendance would have deemed this fact alone an adequate defence; but here were the poor innocent ether and "the heads of the profession," and it was extremely convenient to turn them to some account. The death of the woman created that sort of public excitement which requires, as in the Hounslow case, that blame should, justly or not, be cast somewhere. The moral courage of the surgeons deserted them. "Here is the ether," say the panic-stricken surgeons. "Much obliged to you, gentlemen," says that worthy *gobemouche*, the public. The many-headed monster likes a marvel, especially if a novelty: it took the explanation and was silent.

SANITARY REFORM.

ALTHOUGH Lord Lincoln assures us that the Sanitary Bill of Lord Morpeth is not more comprehensive nor more perfect than that introduced by himself a session or two since, we yet cannot forbear looking at it with more respect, and connecting with it happier auguries. Lord Morpeth has had the happy distinction of securing, not only the sympathies but the confidence of his countrymen; and, perhaps, there never was a statesman who, with the same freedom from meretricious distinctions, possessed at the same time so largely at once the good wishes and esteem of the public. There is a prestige of success, as of high desert, in the noble lord's enterprises; and, hopeless as we were a few years since of large social legislation, we are fain now to confess that the state of public opinion on the one hand, and the possession of so eminent a parliamentary exponent on the other, dispel despondency, and justify the highest expectations for the future.

We are not among those who would undervalue, either as regards classes or parties, the distribution of political power: we will even add, that when national contentions are, in fact, but adroitly disguised encounters of individuals for place and patronage, we can still not survey them with indifference; but the great truth still lies untouched, that the public weal of this country has been overlooked and seriously

damaged by the ceaselessness and continuity of these interesting and interested struggles. While men have been wasting energies and time in lifting political *athletæ* into an eminence too often used for individual aggrandizement,—while a whole people has been agitated on the question, whether a man of this political designation or that political colour shall have a voice in the Parliament of a nation or the councils of a Sovereign—and all this without any result, direct or indirect, as regards the *material* interests of the excited multitude—evils actual, personal, physical—crushing individually, and weakening nationally—have been allowed to exist unnoticed, uncared for, without one single effort being made for their removal! The sectional interest submerged that of a country; and questions of speculative, abstract political economy gave the go-by to the most obvious teachings of common sense and ordinary prudence.

A change in this state of affairs has now come, and social amelioration's promise, if not to take the absorbing interest which is due to them, to compete at least with less practical discussions for the attention of the Government, the press, and the public.

It would be an interesting question to consider what annually must be the loss, we will not say of health, or life, or comforts, but of that mercantile item, CAPITAL, from the innumerable agencies at work in all our towns and cities, for the destruction of the source of all—industry and labour, and, therefore of wealth—physical vigour. We have only to suppose that of the four or five hundred or more who weekly die, through causes which have no existence but in a bad administrative Government, that one half are skilled mechanics, to see that the annual loss thus arising to a country would, if allowed to accumulate for centuries, be equivalent to the riches of many a continental nation. Calculated individually, either in reference to the expenses incurred in producing one man's skilled labour, or to the results which his industry and ability would generate in the course of a few years, the amount cannot even in a single instance but be rated considerable. In that individual's position let us suppose ten thousand, and what a vast loss have we of those results which aggregately make up national wealth! But it is not the destruction of life that alone entails these losses; that impairment of health which precedes death is almost as fatal to the fruition of the artificer's capabilities. Thus, then, we put it: the immense extent of sickness engendered by malarious agencies is a large loss in a country's means; the numerous deaths which not only diminish, but cut off altogether, so much useful labour, are still more destructive of national well-being. And if, taking into account the nature of those agencies—as confined workshops, unhealthy employments—we admit that they powerfully affect the most useful, the most wealth-making, the most skilful of this country's labourers, what further reflections must arise to us when, viewing them in their family relations, we think of the thousands thrown into destitution and

dependence by that impairment of health and that loss of life! If we could analyze the facts of misery, wretchedness, and pauperism, how many of them might be traced home to those malarious influences which for so many years have been privileged as though they were vested rights, and legislated for as recognised and well-sanctioned calamities! Thus, on one side, the means of wealth are swept out of the country, as though they were its curse and affliction; on the other hand, pauperism and disease are legislated for, created, and extended, as though they were a blessing. And while this curse-making, calamity-breeding system is dominant over a whole country, the population, decimated by its influence, may be seen shouting for a party colour, or fighting for a factious by-word!

THE COLLEGE OF SURGEONS AND ITS FELLOWS.

WE have another of the absurd acts of this misguided body to add to the multitude which has made it the most unpopular corporation in the kingdom. It appears that the Council, wishing to erect some collegiate monument to Hunter, and not venturing to proceed on their own authority, invited a select vestry of fellows—and with them entered on the important deliberation. The country fellows were of course omitted in the invitations: so were also many of the town fellows: the whole body of members were, of course, totally neglected. Great dissatisfaction has arisen; and the fellows have been taught to feel that, however proud of their *imperium*, there is in it another *imperium* which practically supersedes their corporate consequence.

INQUESTS ON MEDICAL MEN'S SKILL.

So many correspondents have addressed us on the inquest held on Sir Wm. Curtis, by the West Middlesex Coroner, that we are reluctantly obliged again to drag (to us) an odious topic under professional consideration. No extent of care, no amount of reluctance, can protect us from this inconvenience—not to say nuisance—in the discharge of our editorial functions. We must note, and noting cannot praise. The friends of Sir Wm. Curtis, on his attack by apoplexy, send for his medical attendant, Mr. Freeman; other medical men might not have been at home, most probably would have less understood the case of the patient: yet the friends are lectured in open court for sending to the surgeon who knew the case, and was at home alike ready and capable promptly to render assistance. They should have sent, forsooth, to the nearest medical man, without reference to the fact whether that nearest medical man might be at home, might understand the case, or would venture on the responsibility of its treatment.

Mr. Freeman, a most respectable practitioner; is not only promptly on the spot, but immediately resorts to efficient treatment; he does all which, on his responsibility as the patient's medical adviser, he feels it right and prudent to do. What does the coroner? He establishes

himself as the inquisitor into the surgeon's practice, and, finding by his questions that Mr. Freeman bled his patient, held up his hands before an open court, and the reporters who were to convey his censures to the world, at the alarming ignorance and dreadful malpractice of this most respectable and accomplished surgeon.

Nay, the coroner went further: he favoured Mr. Freeman and the jury—and through them the public—with a valuable lecture on the superiority of cupping. Why Mr. Freeman had not a cupping-glass with him, and did not employ it himself forthwith, were to the worthy coroner matters of scientific wonder and magisterial reproach. In fact, if the medical orthodoxy of the coroner were beyond dispute, the jury might reasonably doubt whether had practice or apoplexy killed the unfortunate baronet. And this is the way in which medical men have their practices criticised, and themselves held up to public obloquy and distrust, by a medical coroner of their own election! Were they more humble or more spiritless than we witness them on occasions, when Public Virtue makes her sure appeal to them, we should fancy they deserved the treatment they obtain. As it is, we must acknowledge that they get even more than they pay for! But, if we say more—we shall pay for more than we get!

MISCELLANEOUS CORRESPONDENCE.

THE ANNUITY FUND.

[To the Editor of the Medical Times.]

SIR,—The noble cause which Mr. Daniell, of Newport-Pagnel, has lately advocated in your journal (a) with so much zeal and eloquence, has long occupied my mind, and excited in it the deepest interest. Four years ago, I wrote respecting it to the editor of a leading medical journal. My reiterated applications were treated with an apathy and neglect, most assuredly unmerited by the cause, however they might be justified, in the editor's opinion, by the impotence and obscurity of its advocate.

In the commencement of the present year, utterly ignorant of the labours of Mr. Daniell in the great and good cause, to the advocacy of which it is devoted, I wrote the following letter. Severe indisposition has alone prevented its earlier appearance in your columns, on all occasions so liberally thrown open to those who labour, like myself, for the promotion of the honour and the interests of our profession. Although my embryo plan will now, probably, merge in the more mature and, in some respects, more comprehensive project of Mr. Daniell, I have decided on the publication of my letter in its original form, accompanied by this necessary explanation, especially as, with the same objects in view, it develops a plan somewhat differing in detail from that proposed by the Newport philanthropist.

With many thanks for the kindness and the courtesy which I have invariably experienced from you, I beg leave to subscribe myself, most obediently yours,

SHIRLEY PALMER.

Friday, March 26.

LETTERS TO THE MEDICAL PROFESSION OF THE UNITED KINGDOM.

LETTER I.

GENTLEMEN,—In commencing my address to

(a) Of this project a prospectus was very partially published last summer. A more detailed exposition of it will, ere long, be widely disseminated among the members of the profession.

you, I shall state three propositions; which few, I calculate, will be hardy enough to controvert.

A body of men better educated, more lofty-minded and enlightened, more benevolent, zealous, and useful, than the regularly-educated physicians, surgeons, and general practitioners of medicine in this country, society contains not within its bosom. In all these great and estimable qualities of intellect and character, they yield not a tittle to the members of the other learned professions. Let their noble and disinterested conduct, on the introduction of vaccine inoculation by the immortal Jenner, be contrasted with the selfish clamours raised by gentlemen of the law, against the late beneficent institution of county-courts for the recovery of debts; and the professors of our philanthropic art will suffer nothing from the comparison.

For the inestimable services rendered by them to society—for the labour, hardships, and privations, which they incur in the discharge of their important, harassing, and frequently perilous duties—no class of men is, in general, so miserably and inadequately remunerated as the class of medical practitioners.

When, as frequently happens, both in town and country practice, the income of the physician, or surgeon-apothecary, does not reach, or exceed, £500, and he possesses no private source of emolument, it is utterly impossible that, in the sad event of his early separation from them by death, he can, even with the most rigorous economy, make a suitable provision for a wife and family. He is expected to sustain, both at home and abroad, the character and appearances of a gentleman; and it too often happens, especially in country practice, that his time and energies are so exclusively absorbed by the acquirement of his moderate income, as to allow not of his paying the necessary attention to the details of its expenditure. Hence, when stricken by the hand of death, the medical practitioner too often leaves his worldly circumstances in a state of perplexing embarrassment, if not of utter and irretrievable insolvency. Many times, has it been my painful lot, within the last forty years, to see the dying moments of a generous and noble-minded fellow, who had sacrificed health and life to the service of those around him, embittered by the agonizing thought that the wife of his bosom, and a beloved and helpless family, would be left to the pity and neglect of a cold and calculating world.

For the widows and orphans of our clergy, many noble institutions have been provided. Of these, the fair edifice, raised by the munificent hand of the late Mr. Newton, in the city of Lichfield, affords a gratifying example. The "Ravens of the Law" line their nests too craftily, during even a short life, to require for their bereaved families any such forethought or provision. But, for the heart-broken widow and destitute children of the zealous and benevolent medical practitioner, cut off by accident or infectious disease, or worn down by incessant anxiety and toil, in the meridian of life, no such institution—no such haven of refuge yet exists.

There are, indeed, "medical benevolent societies" established in the metropolis, and in divers provincial districts of the kingdom, which proffer an allowance of some £50, a year to the widow of every medical man who, during a certain period, has regularly paid up his annual contribution to the general fund. But what will avail this paltry pittance for the maintenance of a lady who has frequently been bred up, not merely with the comforts, but with all the elegancies, of polished life around her; especially if she be left with a family of helpless children to provide for? Nothing short of a fund which shall supply an annual allowance of £120, or make up that sum if she possess a smaller income, to the widow of a contributor, and of £45, each, to one or two of his children, until he, she, or they shall be capable of self-support, or shall have attained a certain age, will remedy the evil of which I complain, and which every feeling mind must deplore. There are, at present, in the European dominions of the British Sovereign about

18,000 regularly-educated practitioners of medicine. If only one-third or two-fifths of this great body could be induced to subscribe from two to four guineas annually, what a noble fund would at once be raised for the most beneficent of all beneficent purposes! And I am not without hope that the childless and more opulent members of our own profession, might occasionally erect a monument, as splendid as imperishable, to their own memory; and the wealthy of other classes, who may have been rescued from suffering or death by the invaluable attentions and resources of our beneficent art, sometimes acknowledge services which no gold can remunerate, by pecuniary contribution or bequest to our widows and orphans' fund.

There are few medical gentlemen in circumstances so needy and depressed that they will be unable to pay an annual contribution of from two to four guineas for such purposes. And with what ineffable feelings of peace and self-respect will the harassed practitioner lay down his head, at night, upon his pillow, when reflecting that, by the sacrifice of one convivial party, or self-denial in the indulgences of the table, to the amount of one or two dozens of wine, annually, he has been enabled to make a comfortable provision for his family, in the event of his own death.

I am about to embark in a literary enterprise, from which, considering the high practical value of its objects, some emolument may be reasonably anticipated. Such emolument, whatever it be, with the leisure and energies of the remnant of my life, I will zealously devote to the promotion of the great—I had almost said the holy—cause which I have here so earnestly, however feebly, advocated. Success in such a cause will constitute a proud and grateful recompense for the many difficulties through which I have been doomed to pass; for the cold neglect, the bitter calumnies and scorn, with which my professional services, character, and acquirements, by them who know me not, have too frequently been requited and assailed. And sweet will be the reflection that, whatever be the result of this earnest appeal to the highest feelings and interests of our noble but neglected profession, the voice of the widow and of the orphan will cheer me onward in my arduous path, and invoke the blessing of Almighty God upon my projected labours.

I have the honour to remain,
Gentlemen, your friend and fellow-labourer,
SHIRLEY PALMER, M.D.
Birmingham, Thursday, Feb. 18.

CORONERS AND MEDICAL MEN.

[To the Editor of the Medical Times.]

Grantham, March 3.

SIR,—I take the liberty of addressing a few lines to you; relative to what ought to be the proper course for a coroner to pursue, as regards requiring, or dispensing with, the attendance of a medical man at an inquest, more particularly when a person has died from the effects of an accident, and a medical man has been in attendance upon him between the receipt of the injury and his death. The coroners here are frequently in the habit of dispensing with the medical evidence, it is said, to save the expense of the fee; and, as I am doubtful in my mind of the legality of such proceedings, I wish to know your opinion. My motive is not to obtain the fee, but, if my opinion is correct, to take proper measures that the law shall be obeyed, the more particularly as several jurors have remarked strongly upon the omissions I allude to. I will just relate two cases in point, upon which I hope you will be kind enough to give your opinion, and any other remarks you may think necessary.

1. A man, in a state of intoxication, fell into a copper of boiling wort, and was much scalded about the arms and chest, and a little on the head; I was called in, and saw him a few minutes after the accident. To be short

with the case, the man died the third day, from nervous exhaustion, and I was in attendance upon him up to the time of his decease. An inquest was held upon him the next day, and I received a note from the coroner, stating that my presence would not be required, as he was in the habit of dispensing with the medical evidence in such cases; at the inquest remarks upon my absence were made by several of the jurors, but I was not sent for.

2. A man was knocked down by a beast, which was being driven into the town to be slaughtered; I saw him about twenty minutes after the accident: he was then insensible, and had strongly marked symptoms of concussion, which quickly ran on into those of compression, and went on from bad to worse. The man eventually died about eighty hours after the accident; no fracture of the skull or depression could be detected, and it was doubtful whether the case was one of laceration of the brain, or fracture of the base of the skull. Unfortunately he had been four years blind of the eye on the opposite side to that on which he received the blow, so nothing could be gleaned from it, and the pupil of the other eye was very slightly dilated, but acted sluggishly upon the stimulus of light, until a very short time before his death. The friends would not allow his head to be examined. An inquest was held, and the jury were occupied more than three hours in the investigation; and remarks were again made by some of the jurors relative to my absence; but I was not sent for, nor did I receive any intimation from the coroner (not the same as in the previous instance), to say whether my attendance would be required or not. My own opinion is that the omission, in such cases, of the medical evidence, is, to say the least of it, incorrect, if not illegal; and I wish to know whether the coroner is empowered to dispense with it. If you think the matter of sufficient importance, I should feel obliged by your inserting this and your answer in your next number, as similar circumstances may have occurred elsewhere; or answer it as you may think fit.

Whilst my pen is in my hand, I may as well take the opportunity of expressing my pleasure at the result of Wakley's attempt to obtain a rule against you, and my approbation of the line of conduct pursued by you relative to the Hounslow case, and to say that I shall have great pleasure in adding my mite to any subscription that may be set on foot, as proposed by "Fiat Justitia," in your number of the 20th ult. To conclude, allow me to subscribe myself,

Yours, obediently,

A SUBSCRIBER AND WELLWISHER.

[We have occasion for reserving our opinions on this letter for a week or two. It is open to the remarks of any of our correspondents.—Ed.]

THE EDINBURGH INFIRMARY AGAIN!

[To the Editor of the Medical Times.]

Sir,—In your last week's "Notice to Correspondents," you remark that "A MEDICAL STUDENT'S defence of the Edinburgh Infirmary forgets its object in wordy abuse of Dr. Thompson." And you add—"Father no defence was necessary, or our correspondent has wholly failed in his design." From this it would appear that Dr. Thompson's wholesale denunciation of the infirmary students—so *mis-called*, as he terms it—has awakened the ire of one of the neophytes of the profession. This was scarcely to be wondered at, considering the very libellous nature of the charge, which confounded the implied mismanagement of the hospital with the students—the active and the diligent, the lazy and the loitering, being all put in the same category! Was not this, on Dr. Thompson's part, "forgetting the object," in something not far from being akin to "wordy abuse"? Let this, however, be as it may, did Dr. Thompson's letter really require an answer? Did it not, in truth, really answer itself? To me the letter

appeared, to borrow a simile from the late Mr. John Bell, of Edinburgh, "a mere explosion, which, like that of an unskilful engineer, instead of scattering the enemy, or overturning their strong towers, blows his own ranks into the air! And I do love (adds Mr. Bell) to see the engineer hoist with his own petard." Has not, in reality, Dr. Thompson, set up a man of straw, for the mere purpose of showing how he can, by pointless vituperation, demolish him?

• Dr. Thompson denounces all connection (unless I very much misunderstand him) betwixt an hospital and a medical school. And are we, in the middle of the nineteenth century, to be told that all clinical instruction, as conjoined with hospital practice, shall henceforth cease, from some apprehension, real or imaginary—though the latter would appear to be its true nature—of evils never before heard of to the patients in our various humane establishments for the cure or relief of disease? That these evils are *imaginary* seems beyond a doubt, so far at least as applies to the Edinburgh Infirmary: for, notwithstanding all the vituperations that have been unscrupulously indulged in since the famous *doquetting* affair came above board in March, 1844, the reader will be astonished to learn that, neither before that period, nor since, has a *single instance or charge of neglect* been brought forward against physician or surgeon of the Edinburgh Hospital. To what, then, do Dr. Thompson's implied charges amount? or, in fact, do they contain anything farther than that the *sic volo, sic jubeo* (as we hinted at in a former letter), of managers *annually elected*, ought, without reasons assigned, to be held as the whole rule of conduct and direction to hospital surgeons and physicians? If so, Dr. Thompson has strange opinions of what is due to the members of a liberal and, as we have been accustomed to consider it, independent profession.

Away, then, with such spurious humanity, as, while it would reduce our best hospital surgeons and physicians to the condition of mere ciphers, would deprive the public of one of those very means that can alone ensure either able surgeons or good physicians. So thought not the biographer of our venerable Pott—for half a century, or "man and boy," as he termed it, surgeon to St. Bartholomew's. "The beneficial influence of hospitals is not shut up within their walls, nor confined to the objects who are there relieved; the blessings which are there distributed revert to their opulent and noble supporters, and are extended to all ranks and conditions of men, by the improvements which the medical art receives from the students who frequent them." And, Mr. Editor, as regards Dr. Thompson's more than implied charge of inutility—to say nothing of the inhumanity—of the clinical teaching and practice of the Edinburgh Infirmary, do not the lectures of a Fergusson and a Wright, which adorn your useful pages, afford ample refutation—seeing that both these gentlemen were pupils in that institution?

As regards some other points contained in Dr. Thompson's letter, it is not my intention to enter, seeing they are more of a personal than general nature. One thing, however, seems clear, that, till a specific charge is made and supported by something like tangible testimony, it would conduce more to the interests and honour of the profession, altogether to avoid troubling the public with matters tending to inspire anything but confidence in the afflicted sufferers, whose rank and situation compel them to have recourse for relief to our public medical institutions.

AN OLD INFIRMARY PUPIL.

Banks of Lochleven, March 22.

AGENT FOR RESUSCITATING PATIENTS AFTER INHALING THE VAPOUR OF ETHER.

[To the Editor of the Medical Times.]

Sir,—For the last week, I have been, using as an agent for resuscitating patients after inhaling

the vapour of ether, pure oxygen gas, with the most perfect success. To-day I operated in nine cases on the teeth; to each patient I administered a full dose of the vapour of ether; and subsequently a few inhalations of oxygen. In not one case did the patient complain of debility, &c., but recovered perfectly in less than a minute and a half, timed by the medical men present.

I will, by your permission, furnish, in a future number of your journal, the details of these and other experiments with oxygen.

I remain, Sir, your obedient servant,

F. ROBINSON.

7, Gower-street, Bedford-square, March 29.

HOUSE OF COMMONS—TUESDAY.

HEALTH OF TOWNS.

Lord MORPETH, pursuant to notice, moved for leave to bring in a bill for improving the health of towns. He said, that though he felt the matter which it would be his duty to bring under their notice was one of very great importance, yet, not to mention his knowledge of the fact that some part of that evening had been occupied with other business, he wished, on different grounds, to avoid all unnecessary prelude or preface. The subject of public health was a matter which had occupied lately a great deal of attention; but, within most of their memories, the time had been when very little, if any, regard was paid to it. Now, however, the general sentiment seemed to be, that it was one which ought to occupy very seriously the thoughts of Governments and Parliaments; and the great body of the people were of that opinion, and very much busied their minds with its principles and details. He should, in the first place, proceed to mention the several stages through which the question might be said to have passed, and the inquiries to which it gave rise, and, with the permission of the House, he should now proceed to lay before them the following statement of the various steps taken in this inquiry:—

"1838, May 12.—Report made to the poor-law commissioners by Dr. Arnott and Dr. Kay on the prevalence of certain physical causes of disease, which might be removed by proper sanitary measures. A similar report by Dr. Southwood Smith, exemplified in the present condition of the Bethnal-green and Whitechapel districts, as ascertained by a personal inspection.

"1839, April 29.—Report on the prevalence of fever in twenty metropolitan unions by Dr. Southwood Smith. 5th Report of Poor-law Commissioners, Appendix C, No. 2.

"August 19.—Address to the Queen by the House of Lords for an inquiry and report similar to the above throughout England and Wales.

"August 21.—Letter from Lord John Russell to the poor-law commissioners, desiring them to cause such an inquiry to be made.

"1840, Jan. 28.—Letter from the Marquis of Norraaby, desiring them to extend the inquiry to Scotland.

"1842, July 9.—Letter from the poor-law commissioners, transmitting to Sir J. Graham the report made to them by Mr. Chadwick on the sanitary condition of the labouring population of Great Britain."

In 1843 a commission was issued by Sir R. Peel's Government to inquire into the same subject. In 1844 they made their first report; and in July, 1845, a bill was brought in by the Earl of Lincoln to provide for the sewerage and drainage of towns, which was ordered by that House to be printed. Thus, it would be seen that all political parties had contributed alike to the progress of this measure, and that, if any effectual measure on the subject were ultimately carried, the praise of having done so could not be monopolized by any one party in the state, but must be divided among several successive Governments, and among different parties—(Cheers). He (Lord Morpeth) would endeavour to place before the House the main facts on which the proposed measure would be founded—the results that had been developed in the progress of these inquiries, whether official, parliamentary, or sta-

tistical. He preferred now to give the leading facts and results rather than a mass of particular instances, which details he would reserve for a future period; and, in acquitting himself of this part of his task, he felt it was quite unnecessary for him to disclaim any pretension of using original matter, or even of giving to the matter he should use any novelty of form. The main strength of his case lay in the fact that the evils which had led to the introduction of the measure which he was now about to propose were so generally felt and so loudly complained of. Several persons of great accomplishments and ardent benevolence, both in and out of the House, had taken great pains, in a way that did them infinite credit, to inform and excite the public mind on the subject, and if he now, mainly by the accident of his position, found himself at the eleventh hour bringing forward a measure to accomplish their objects, he begged to proclaim that he was doing so because he had been a gleaner from their stores, and had been able to avail himself of their previous efforts. The difficulties of the case were too numerous, and the opposing interests that might be alarmed by the interference of the Legislature were too formidable, to allow him (Lord Morpeth) to dispense with any assistance he could bring to his aid, from the labours of those who had preceded him, in putting his case before the House and the public, which he would do as briefly as he could, consistent with the necessity for making a fair and honest statement. Before stating the nature of the measure he would first lay the foundation by stating the facts on which it was a superstructure. From a statement drawn up by Dr. Guy, physician to King's College Hospital, from the reports of the registrar-general, it appeared that the relative mortality in the town and country districts was as follows:—Population to the square mile, country, 199; town, 5,100. Annual deaths in 1,000,000, country, 19,300; town, 27,073; annual excess in town districts, 7,773. Rate of mortality, country, 1 in 52; town, 1 in 37. He also supplied further particulars as to the rate of mortality generally:—England, 1 in 45; Isle of Wight, 1 in 68; Anglessea, 1 in 62; London, 1 in 39; Leeds and Birmingham, 1 in 37; Sheffield, 1 in 33; Bristol, 1 in 32; Manchester (union), 1 in 30; Liverpool (parish), 1 in 29. Thus the inhabitants of London, compared with England at large, lost 8 years of their lives; of Liverpool, 19. The population of large towns in England being 4,000,000, the annual loss was between 31,000 and 32,000. But all towns were not necessarily so unhealthy, as appeared by the following statement:—Liverpool, deaths per 1,000, 35; Manchester, 32; Bath, Coventry, Derby, Dudley, Shrewsbury, and Sunderland, 26; Carlisle and Norwich, 25; Tynemouth, 23; Halifax and Kidderminster, 21. Lord Ebrington, in his inquiries on the effect of high wages and good food, said:—"That of the south-western district, which includes Cornwall, Devon, Somerset, Dorset, and Wilts, is only 1 in 52, not 2 per cent., while that of the north-western, including Cheshire and Lancashire, is 1 in 37. Now, let it not be said that this is owing to extreme poverty and want of the necessities of life; the condition of the labourers of the west, the badness of their dwellings, the lowness of their wages, the consequent scantiness of their food and clothing, have been the subject of public animadversion. With the exception of the Cornish miners, the condition of the labourers throughout the western counties is described as nearly the same; yet in Wiltshire, the county of lowest wages, the deaths are 1 in 49; in Lancashire, 1 in 36. The average age at death in 1841 was, in Wiltshire, 35 years; in Lancashire, 22; at Liverpool, 17; that of the labourers in Wiltshire, 33; operatives in Liverpool, 15. At Manchester, in 1836, the average consumption per head of the population was 105 lb. of butcher's meat, about 2 lb. a week, exclusive of bacon, pork, fish, and poultry (what a different average would our country produce!); the average age at death was 20. The proportion of paupers in the 15 principal agricultural counties is 1 in

8; in the 12 principal manufacturing counties, 1 in 13; in Lancashire, 1 in 11; and of the deaths in 8,500,000 of town, and about an equal number of country, population were, respectively, in 1838 and 1839 together—country, 1 in 54.91, of whom above 70, 20 per cent.; town, 1 in 38.16, of whom above 70, 9 per cent.; all England, 1 in 46.00, of whom above 70, 14 per cent." The following was Dr. Guy's statement of diseases which occasioned the excessive mortality of large towns:—Deaths in 1,000,000 from smallpox, country, 500; town, above 1,000; from measles, country, 350; town, 900; scarlet fever, country, 600; town, 1,000; typhus, country, 1,000; town, 1,250; epidemic and contagious disorders together, country, 3,400; town, 6,000. Waste of life in towns under this head, 2,600 a year. Diseases of infants.—Teething, convulsions, water in the head, country, 1,300; town, 3,500. Waste of infant life under this head, 2,200 a year. Scrofulous diseases and consumptions, country, 3,800; town, 4,000. Total excess of deaths, 5,500 in the million. So that there was a waste of 22,000 lives in the 4,000,000 inhabiting large towns. Dr. Guy also said, that "The total number of deaths in England and Wales during the year 1841 was 343,847, or somewhat less than 1,000 a day. Now, this is at the rate of one death in 46 inhabitants. But if instead of one death in 46 inhabitants there had been one death in 50 inhabitants, or two per cent., no less than 25,107 lives would have been saved. Now, all men who have paid any attention to this subject agree in the opinion that, by proper sanitary measures, it is possible to ensure such a state of health among the community at large that the mortality shall not exceed that proportion. If the sanitary state of the entire country could be raised to the condition of the most healthy counties, so that instead of one death in 46 inhabitants there should be only one death in 54, we should have an annual saving of no less than 49,349 lives, or about one seventh of the whole number of deaths! At first sight it may appear extravagant to represent such an improvement of our sanitary condition as possible; but when it is recollected that, on the one hand, even our most agricultural counties have not yet attained to their best sanitary state, and that our large towns have been hitherto almost entirely neglected, and admit of immense improvement, the attainment for the whole country of a sanitary condition represented by one death in 54 inhabitants is at least within the bounds of possibility." Dr. Southwood Smith said:—"In some localities there was not a single house in which fever had not prevailed, and in some cases not a single room in a single house in which there had not been fever. The districts in which fever prevails are as familiar to the physicians of the Fever Hospital as their own names." Further still, Dr. Lyon Playfair calculates that for every unnecessary death there are 28 cases of unnecessary sickness; consequently, in our large towns, above 700,000 cases of unnecessary sickness. The same calculation in the metropolis would save 10,000 deaths, and 250,000 cases of unnecessary sickness. But were all parts of our large towns equally unhealthy? In one of the reports of the registrar-general it was stated that the metropolis is divided into three groups of ten districts each, under the title of the healthiest, the medium, and the most unhealthy districts. The result was as follows:—10 healthiest, with an allowance of 202 square yards to each person, have a mortality of 1 in 49; 10 medium, with an allowance of 102 square yards to each person, leaves a mortality of 1 in 41; 10 unhealthiest, with an allowance of 32 square yards to each person, leaves a mortality of 1 in 36. The Rev. Mr. Clay, of Preston, makes four classes of streets:—Well conditioned, mortality among children under 1 year, 15 in 100; moderately, 21 in 100; ill, 30 in 100; worst, 44 in 100, or three times as much as the first; and it appeared, from tables prepared by Mr. Chadwick, that in St. George's, Hanover-square, the average age at which the gentry die

is 45; labourers, 27; St. Giles's and St. George's, Bloomsbury—gentry, 40; Liverpool working class, 17. Now, the documents of most authority on this subject were the quarterly returns of the health and mortality made up from 115 districts of England by the registrar-general for the quarter ending June 30, 1846. From this report it appeared that 43,582 deaths were registered in the spring quarter ending June 30—a number greater by 2,863 than were registered in the corresponding quarter of 1845, and 4,741 more than in the June quarter of 1844. If the mortality had not been higher in the towns than in the poor country districts, where the air is pure, the deaths in the quarter would not have exceeded 33,000. Within the last three months 10,000 lives have been destroyed in a part only of England by causes which there was every reason to believe might be removed. The report went on to say that "the inadequate supplies of water by companies, the imperfect sewerage in towns, the open drains and ditches, and the general neglect of cleanliness, leave everywhere large quantities of organic matter to decay and putrefy in the midst of crowded populations. In such circumstances the mortality, like putrefaction, is always increased when the temperature is high, and epidemics of diarrhoea, dysentery, and cholera prevail. He had felt himself constrained by the necessity of his position to trouble them with these proofs, this enumeration of existing evils, before proceeding, as he now would do, to mention the main provisions of the measure the Government proposed to introduce, in the hope of remedying those evils which could be remedied, and of mitigating those which could not. In such a state of things as that which he believed he had proved to exist, he took it that it would at once be admitted the state had a right to interfere. He knew there were many, for whom he entertained a high respect, though he did not agree in their opinions in this instance, who thought that the state had no right to interfere in education as to what concerned the domain of mind; but, in cases that were essentially physical and material in their nature, which concerned causes that affected the health of large masses of the population, and the happiness of persons in towns and cities, and which could not be removed except by some powerful intervening central authority—in such cases, he thought it would be a waste of words to prove that it was at once the right and duty of the state to interfere. Then the next question to be asked was through what agency should the state exercise that degree of interference, that superintending power, which he thought it would be admitted ought to be assigned to? Lord Lincoln's Bill, on which he did hope to found the greater part of the proposition he had the honour to submit, made use for this agency of the Secretary for the Home Department, with occasional assistance from the Privy Council. The committee of the Metropolitan Health of Towns Association, however, published a very full and able report on the provisions of that bill, of which a considerable portion was occupied by remonstrances against that use being made of the Secretary of State, on the ground of his time being already more than engrossed by the onerous and multifarious duties of his own department. They reported that, besides the general superintendence of the large internal affairs of England, Scotland, and Ireland, he had, also, the ultimate superintendence of the police, of prison discipline, and of the poor-law, in the United Kingdom. These statements were tantamount to proof that the Home Secretary could not properly be burdened with this addition to his duties, and her Majesty's Government felt that, whoever might be the person who filled that high department, whether he had the aptitude for business of its late occupant, or that of his right hon. friend who now filled it, it was not wise to that accumulation of business in that office to add the new and busy calls of an extensive and laborious duty. The same reasons, it was considered, would apply to any department which had a large amount of business of its own

Some persons, however, had suggested the committee of the Privy Council as a fit body, but that committee did not happen at this moment to stand in very great esteem with all classes of this country; and her Majesty's Government thought, also, that for duties that were required to be always in operation such a body were not adapted to the uniform discharge of them, especially if the members of the Government of the day were not also members of that committee. It was, therefore, thought that the business in hand was important and copious enough—(hear)—together with the functions which would be attached thereto, to justify the constitution of a special board for the purpose, framed on the same footing as the Railway Board of last session. It would consist of five members, three of whom would be paid members, one a member of the Government, who would not be a paid member, and the other the First Commissioner of Woods and Forests, who would be *ex officio* chairman of the board. This board, which would be called the Board of Health and Public Works, would be empowered, either on the petition of any town or without such petition, to direct an inquiry to be made into the sanitary condition of such town or district. They would be empowered to appoint inspectors or recommend them to the town in question, who would go down to the district and institute the necessary inquiries; they would make a sufficient and adequate survey, point out the direction of rivers, streams, and water-courses, suitable for assisting in the drainage, and define the proper area of any works to be carried on. The board, if necessary, would consider the reports of these inspectors, and the objections made to them; and they would then recommend that an order in council should issue, conferring the necessary powers upon some local administrative body. The questions which then arose were, what ought to be those powers, and how ought the local administration to be constituted? The Government might have taken the old and constitutional mode of appointing commissioners of sewers and drainage, which was as old as the time of Henry VIII, namely, by nomination direct from the Crown. But, as the powers ordinarily exercised by commissioners of sewers did not provide sufficiently for the construction of house drains in connection with main sewers, or a sufficient supply of water, and as the cardinal point upon which all the recommendations, inquiries, and representations turned was, that it was absolutely necessary that the powers of sewerage, drainage, paving, and cleansing the streets, and the supply of water, should be placed under the same control and jurisdiction, the Government proposed to give all the powers which he now enumerated to the body which would be appointed to carry out on the spot the necessary functions entrusted to them. But what would be that body? It had not been found necessary to embody all their functions in the present bill, because many of them had been included in bills brought in during the present session, some of which had passed that House, and which combined the powers heretofore held by conflicting local administrations. The bill of the noble lord (the Earl of Lincoln) provided for the election of a newly-elected body; and the greater portion of that bill was taken up by clauses which regulated the boundaries of electoral districts, divided wards for the purposes of elections, defined the manner of voting, and instituted a new and complete electoral system. The present Government thought, on the other hand, that there was quite enough of elections going on in the country, and that what with the elections of town councils and poor-law guardians it was hardly desirable to engraft an entirely new electoral system for the creation of a body analogous to the town councils in many respects. They considered that these bodies would be composed of very much the same sort of persons in most towns as these in town councils; that they would be elected, to a considerable extent, by the same constituency; that their

attention would be directed to very similar purposes; and there was good reason to apprehend that jealousies would arise between two zealous, counteracting, and mutually repellent bodies. It had been suggested by some persons that these bodies should be appointed by the Crown, but a still more hostile and embittered feeling might be created between a body so constituted and the town council. Many persons had felt that it was both inconvenient and unnecessary to have the distinct superintendence of two sets of persons for municipal and sanitary purposes; and it would be acknowledged by those who had given their attention to the subject, in how few hands the practical philanthropy and active intelligence of a district were ordinarily found. This was the basis upon which the Government proposed that the various powers and functions heretofore exercised by these two distinct bodies should be consolidated, and conferred upon that body which was already elected by the inhabitants at large for the good government of their respective communities. Were not these, indeed, the very powers which seemed to be the appropriate object of municipal corporations and town councils? When the Municipal Corporation Act was passed the Legislature did not transfer to the new town councils the powers exercised by the trustees under the local acts. It was perhaps as well that Parliament had not done so. It appeared probable that the town councils would very much engage in party contests, and that any novel powers of this kind that might be given to them would be turned to political purposes. He would admit that the first elections under the Municipal Act did very much incline to one political side, but this could hardly be wondered at when it was considered that the electors were enjoying a new power, and that they had long laboured under a sense of exclusion from municipal power. Subsequent elections, by a very natural reaction, had perhaps given a bias on the contrary side. However this might be, it was clear that the intensity of political excitement had greatly subsided in these bodies, and although they were not wholly free from objections on this ground, yet there was good reason to believe that many more important and useful functions might be given to these bodies now and then when they were more divided by party demarcations—(hear)—and that the effect of so doing would be to tempt valuable and useful men to offer their services. The only difficulty was in the annexation to existing wards of bits of suburbs and offshoots of land suitable for the area of drainage which were not at present included in the municipal boundaries. But the present bill proposed to take these bits of land, and either annex them to the wards contiguous, or make new wards of them when necessary. He was confirmed in the views he had just expressed by the Manchester Health of Towns Association, who made it one of their objections to Lord Lincoln's bill that it created a new electoral body, and who argued that the powers it conferred would be most fitly exercised by the town councils. In some districts tracts of country might be necessary to secure an outlet for the drainage of the district, and the bill gave the necessary powers to carry out this object. In towns which possessed corporations the Government proposed to make use of the existing town councils to carry out the act; but there were places of large size which had no town councils, and which were yet in great want of improvement—such as Brighton and other large towns. They might, in such cases, adhere to the old practice of nominating commissioners of sewers by the Crown, leaving the inhabitants to apply for a charter of incorporation if they thought proper. But they thought it better to give a popular election to the inhabitants of those towns which did not apply for a charter of incorporation. He proposed, accordingly, that the commissioners in these towns should be elected by the ratepayers, and that the Crown, on the recommendation of the Board of Health and Public Works, should nominate as adjuncts

a number not exceeding one third of those appointed by popular election. This was in unincorporated districts. But, did the present act provide for the whole kingdom? It did not refer to Ireland and Scotland. He admitted that the evils which the present bill was intended to remedy were still more crying in those two portions of the kingdom, but he knew from experience that it was to the last degree complicated and perplexing, unless in some very general measure, to deal with all three countries in the same parchment. He hoped that his right hon. friends connected more especially with Ireland and Scotland would give their best attention to the construction and to the working of this bill, and that they would afterwards, furnished with the facts of the experience of England, adapt the present bill to those countries in the way they might think most expedient. The metropolis had been excluded from the operation of Lord Lincoln's bill, but it was proposed to include it in the present bill, and he did not see why it should be excluded from the operation of such a bill. The whole surface of London was now under the control of several distinct boards of commissioners of sewers. He believed there were no less than seven, who exercised their powers in an irresponsible manner. Some of them were complained of for the expensive and inefficient manner in which they discharged their duties, while others gave more satisfaction. He would not, however, go into that, but would state that, on an order in council being issued after the passing of this act, all existing commissioners of sewers would be superseded in the discharge of their functions. The ratepayers in these metropolitan districts would be empowered to elect, as their representatives, commissioners for sanitary purposes, and the Crown would have the nomination of one third the number so elected. It would be desirable to make the metropolitan commissioners more numerous than those of other places, and the Crown would have a proportionately larger choice to make of persons fitted by their knowledge, science, and philanthropy, to aid the deliberations of these boards. The powers given to the commissioners were for sewerage, draining, paving, and cleansing; and he believed it to be essential to the successful working of the scheme that as soon as the act came into operation, and the new commissioners entered upon their functions, all present conflicting local jurisdictions should cease. He therefore proposed that the Crown, by an order in council, should extinguish any local body of commissioners for sewerage, drainage, paving, or cleansing, who might heretofore, under any local act, have exercised any power in any locality. The present conflicting jurisdictions created nothing but confusion, and often nullified the entire proceedings of these bodies. The Manchester Health of Towns Commission had made the suggestion that all the sanitary regulations of a district should be under one and the same authority. Of course provision must be made for debts incurred under present local acts, for contracts made, and for compensation for existing officers. He was aware it was proposed by this bill to make a great swoop upon local acts, and to interfere with a swarm of local commissioners. But the House ought to settle in its own mind what would be, on the whole, the best local body for executing the powers of the act, and, having settled that, they ought not to consider who were in the way, but insist upon the unity of action which was so necessary. Some town councils, it might be said, discharged their duties ill, and, on the other hand, he heard of commissioners of sewers and paving who gave great satisfaction. But having consecrated the town councils for these purposes, having respect to the appointment of members appointed by the Crown, he hoped that the very importance and responsibility of their functions would elicit the intelligence and activity necessary for their due discharge. If, however, this in some instances should, unfortunately, not be the case, the House would have some security in the provisions of the bill.

The report to which he had before referred mentioned those checks and limitations which it was necessary to adopt in order to ensure the efficient working of a measure of this nature. The committee which reported on the bill of the noble lord the member for Falkirk (Lord Lincoln) recommended,—

"That the interests of the community should be protected by the supervision of a competent, impartial, and responsible public officer, named an inspector. That, before new works are undertaken, full and comprehensive surveys should be made by competent engineers. That plans of complete works should be prepared by responsible public officers, locally examined by them with the estimates. That expository reports should be drawn up for local publication, in order that the advantages of new works may be thoroughly canvassed by all parties interested in them. That the whole of the works should be maintained as well as executed by contract. That the performance of the contract should be supervised by a competent, paid, and responsible local officer; and that the true causes of disease and death should be ascertained, and the spread of diseases, more and especially of endemic diseases, should be checked, by the appointment in districts of a skilled and responsible medical officer, called an officer of health."

It was proposed by this bill that an inspector should be appointed, whose duty it should be to inquire what had been done in the towns and districts he might be required to visit, to ascertain what works were wanted, to examine or prepare plans and surveys, and to make reports to the central board. Besides this inspector-general, who he supposed would be an engineer of some eminence, it was proposed to appoint a medical inspector, who should in like manner be required to visit the districts placed under his charge. It had been deemed advisable that this medical inspector should not be actually connected with any particular district, but that he should be disengaged from any local influence that might be brought to bear upon him. In addition to the engineering and medical inspectors, the town councils and commissioners were to be empowered to appoint local surveyors, to be approved by the central board. These surveyors, he apprehended, would be civil engineers, and it would be their duty to superintend the contract works. The town councils or commissioners would also have the appointment of inspectors of nuisances, who would provide for the summary removal of all nuisances that might have an injurious effect upon the public health. Provisions would also be incorporated in the bill for preventing the nuisance of smoke—not smoking—(A laugh). It would be required that, in any building intended to hold great numbers of persons, due provision should be made for securing proper ventilation—(Hear). Provisions would also be introduced into the bill enabling the town councils or commissioners to contract with gas companies, if they should think proper to do so, for the lighting of their respective towns and cities. He would now refer to a subject to which he had before made a passing allusion—the importance of securing an ample supply of water. It would, he thought, be admitted on all hands that a sufficient supply of water was an indispensable accompaniment—indeed, a condition—of all real drainage; and that the existence of drains, if they had not water to carry the refuse matter away from them, would only tend to propagate and increase the evils which they were intended to remedy. The use of tubular sewers, and a proper supply of water, seemed now to be looked upon as indispensable to efficient drainage. He believed it would be generally acknowledged that the supply of water in many places, including this metropolis, was both too scanty and too expensive. There was a great accumulation of argument and of evidence to show how desirable it was to have a constant rather than an intermittent supply of water. He found it was stated by Mr. Toynbee, that "the water is generally

laid on in the yard, and a supply given three times a week, and, at each time the water comes on, the film of dust and blacks that has been deposited on the surface is mixed up with the previous accumulations. The same water is used for making bread, by a baker, who supplies a great number of the poor." Dr. Aldis said, that "the water retained in the rooms of the poor for domestic purposes soon becomes covered with black scum, and there is generally a filthy accumulation on the surface of the water-butts. The fatigue of fetching a proper supply, which ought to be forty-five gallons a day for a cottage, is most wearing." Mr. Hawkeley stated that "it is perfectly well known to those acquainted with the feelings and habits of labourers that they regard it as an intolerable nuisance, on their return home, tired with the day's labour, to have to fetch water from a distance out of doors, in cold or in wet, in frost or in snow." It seemed, indeed, that they had not advanced far since the days of Andromache,—

"to bring
The weight of waters from Hyperia's spring."

This bill would require that the town councils and the town commissioners should supply water to every house; and for this purpose they would be empowered to construct waterworks, to contract with water companies, and, if necessary, to compel the sale of waterworks, securing the full rate of their dividends to those companies from whom it was found necessary to purchase their works. Provision was also made that, in the case of permanent works being required, where any unusual degree of expense would probably be incurred, power should be given to borrow money, and that the principal and interest should be levied by a series of easy instalments, not upon the owner, but upon the occupier, who would be the person to benefit by the improvements. By this arrangement he (Lord Morpeth) hoped they would remove the chief obstacle to the improvements in our towns—the opposition of owners of property to what they looked upon as a serious and immediate expense which was thrown upon them. He knew that it was this question of rates—the hard money to be actually paid—which had hitherto been the direct obstacle, and for some time to come, he feared, must continue to be an indirect obstacle, to the hope of seeing sanitary measures undertaken with vigour and good heart by the inhabitants of towns. There was something in the very sound of rates which was at fearful odds in the balance against health, industry, content, and all the virtues; but he feared that, in the first instance, some additional outlay must be incurred if they hoped to do anything effectual in the way of promoting the improvement of the public health. It was a necessary tribute which property must pay for the safety and lives of the poor, and for those who earned their living by the sweat of their brow, but a tribute which he believed in the long run contributed in no slight degree to the health and enjoyment of those upon whom it was levied. Besides the inestimable advantages which the improvement of the public health would carry in its train, he believed there was good reason to hope that even on the ground of economy the advantages it held out were not to be slighted. He was unwilling to rely very strictly upon any series of calculations which had been made on this subject, but he could not refrain from quoting separately the heads of some calculations which had been drawn up by persons of high and trustworthy character. Dr. Lyon Playfair estimated the loss from unnecessary death and sickness for England and Wales at £11,000,000, and for the United Kingdom at £20,000,000. These were the items of expense which Dr. Playfair reckoned were incurred under the present system, or rather want of system—direct attendance on the sick; loss of what they would have earned; premature death of productive contributors to the national wealth; and expense of premature funerals. Dr. Playfair estimated the loss for Manchester at nearly

£1,000,000; Mr. Hawkeley calculated the loss for Nottingham at £300,000; Mr. Clay estimated the loss for Preston at £990,000; Mr. Coulthart took the loss for Ashton-under-Lyne at £235,000; and Dr. Playfair considered the loss of this metropolis to be above £2,500,000; and estimated the total loss to England and Wales at little short of £11,000,000. Dr. Guy, referring to the health of towns, said,—"I shall say nothing of the liquid manure which, as I have been given to understand, is suffered to drain away into the ditches, thence into the rivers, and from them into the sea, from fully one half of all the home-steads of England; I will speak merely of the unappropriated refuse of large towns. In Flanders, where manure is carefully collected, instead of being, as here, suffered to run to waste, the excreta of an adult is valued at £1 19s.; considering the enormous additions made to this manure in our towns, it will not be thought unreasonable to estimate the value of this part of the refuse which now runs to waste at £2 per head of the population, and, supposing that in England or in Wales the towns which are guilty of this extravagance contain in all only 5,000,000 inhabitants, we shall have an annual waste of at least ten millions of money." Mr. Smith, of Deanstone, also expressed his opinion that—"Taking a general view of the subject, we may assume a clear revenue of the sewer water of all towns of £1 for each inhabitant." Dr. Arnott said that "the value of town manure might be estimated by the fact, that a portion of the drainage of Edinburgh has increased the value of these lands by more than £5,000 a year, and that, if the whole drainage of London could be saved, at a sufficient distance from the town, the value would exceed £500,000 a year." Dr. Arnott observed that Milan had benefited to a great extent by the adoption of such measures as he suggested; and he then went on to say that "it has been calculated that whereas the cess-pools cannot be emptied by nightmen for less than 17s. a year, and whereas water-carriers get 4d. for a pailful of water at the door, an addition of 2d. to the rent, per week, will suffice for the expense of water-closets and of an unlimited supply of water for every house; and that the entire sanitary purposes contemplated under all the recommendations of the Health of Towns Commissioners may be procured for 3d. a week per house." These calculations might be looked upon as sanguine, but those persons who were best acquainted with the subject knew that much was to be done with regard to economy by adopting efficient sanitary regulations. Mr. Holland, of Manchester, stated that in 20 streets in Chorlton-on-Medlock the mortality fell from 110 to 89 per annum, after, and no doubt principally in consequence of, the streets being properly paved and drained. Mr. Gardiner and Mr. Noble had confirmed the result by showing that in certain streets in St. George's district, Manchester, the deaths in 1838-1839 amounted to 495; but that in 1841-42, after the streets were paved and sewered, the deaths were only 432, being a diminution of 53, or about one eighth. In a district in Ancoats, a diminution of 40 deaths out of 270, or about one seventh, followed a similar improvement. But a still more striking illustration of the same fact might be found nearer home. It was contained in Mr. Liddle's evidence before the health commission:—"Windmill-court, in Rosemary-lane, was one of the most unhealthy in my district. It was unpaved and filthy, and with stagnant water before the houses. I used to visit it sometimes two or three times a day for fever cases. About twelve months ago it was flagged; it was well supplied with water from a large cast-iron tank, which enables the inhabitants to have a constant supply, instead of an intermittent one, on three days a week. The court is regularly washed down twice a week, and the drains are so laid that all the water passes through the privy and carries off the soil, which was formerly a most foul nuisance, and a constant expense to the landlord. In the seven months ending March, 1843, I attended forty-

GOSSIP OF THE WEEK.

one new case of sickness in that court; in the last four or five months I have had but two cases. The rent is better paid, and the landlord is considered to have made a good thing of the improvements, which are executed at his own expense. There is no doubt that sickness is the most common cause of the inability to pay the rent." He (Lord Morpeth) need not trouble the House at greater length by quoting from these documents. In a matter so large and complicated many imperfections would, no doubt, be discovered; and many oversights might have occurred in the bill which he now asked leave to lay upon the table. He could say, however, that that bill had been framed with an honest intention and a single view to the public good; and most unfeignedly thankful would he be if the result of that measure, and the consideration it might receive from Parliament, and the ultimate sanction it might obtain from the throne, should do anything to promote the objects which they aimed at effecting, namely, to diminish, as far as they could, those noxious influences within their reach which now so painfully afflicted a large majority of their towns and cities; to hunt down to their source, if it were possible, the prevailing causes of general unhealthiness; to let in more pure air and pure water, and thus to diminish, as far as they were able, those epidemic diseases which now and then had shown their effects in fearful ravages; to wage war, wherever they could, against filth and stenches, and to endeavour to avoid their sure attendants and consequences, bodily weakness, languor, and death-dealing pestilence; and thus, as they hoped, to lengthen the lives and add to the happiness of all classes of their countrymen—(Hear, hear). The noble lord concluded by moving for leave to bring in the bill.

Mr. MACKINNON, in seconding the motion, observed that, to show the great advantages arising from attention to cleanliness and ventilation, he might mention that when Anson circumnavigated the globe seventy years ago, he lost, in his ship the Centurion—owing to the want of proper food, ventilation, and accommodation—270 men out of a crew of 660 men; but it was computed that, if a ship of the same size and of the same complement were now to undertake the same voyage, she would not lose more than five per cent. of her crew from sickness. He regretted that no legislation had been adopted with reference to this important subject at an earlier period; and why, he would ask, had the question been allowed to rest? Because it did not affect either the upper or the middle classes of society, for the results of those causes which were prejudicial to public health were chiefly experienced by the poor.

Colonel T. WOOD thought it would be unconstitutional to give to the Privy Council the power, as proposed, of repealing a variety of local acts.

The Earl of LINCOLN thought he should be acting wisely in abstaining, on the present occasion, from entering at any length into a discussion of the noble lord's proposition. He concurred with the hon. member for Lymington in thanking the noble lord for the introduction of the bill; but he thought the hon. member's congratulation at finding the bill far more comprehensive in its nature than the bill he (Lord Lincoln) formerly introduced was somewhat thrown away, for the noble lord had himself admitted that most of the provisions of his bill were taken from that bill which he (Lord Lincoln) had brought in, and which, with the exception of the provisions for the ventilation of large buildings and for the prevention of the nuisance of smoke (two subjects which the noble lord would probably find more difficult than he contemplated), contained, he believed, all the main sanitary provisions of the proposed bill and many others. He would now only touch on two or three points in respect to which the noble lord's bill differed from his. The noble lord said it was necessary that there should be an intervening superintending central

authority. To a certain extent he (Lord Lincoln) had already given a proof of his concurrence in that principle by introducing into his bill a provision to some such effect. He did not participate in the general condemnation of what was called centralization, but at the same time he thought that the noble lord by his proposal was running the risk of extending the principle too far, and he was afraid that the ultimate, if not immediate, result of the constitution of the body, which the noble lord proposed to create would be a far too minute interference and intermeddling with local affairs, which ought to be left to the parties on the spot, whose interests were involved. By the bill which he (the Earl of Lincoln) had introduced, it was proposed that this central authority should be conferred on the Secretary of State for the Home Department, but only for limited purposes, such as enabling him, upon representation from any locality where the act might be brought into operation, to send down inspectors free from local bias and interests to report, &c. The noble lord also proposed to alter the body to which the central power should be given, setting forth as a reason the vast amount of work which the Secretary of State for the Home Department already had to transact. If this argument were to prevail it would be almost impossible to introduce any bill imposing the discharge of new duties without at the same time creating a new Minister. It should also be borne in mind that it was proposed, by a remodelling of the poor-law commission, to relieve the Home Secretary of a portion of the work he now had to transact; and the duties which the noble lord's bill would impose would not be so onerous as those from which the Home Secretary would be relieved.

Mr. ANGLIMORE rejoiced that the noble lord had undertaken to deal with this subject, and admired his moral courage, and trusted he would have the perseverance to carry this great measure through.

Mr. GURNEY begged to remind the House that there were now twenty bills for the improvement of towns before it, many of them creating new bodies of commissioners for, perhaps, only part of a town. It seemed to him important that those bills should be suspended until this should be disposed of.

Sir W. CLAY was desirous to express his doubt of the expediency of including the metropolis in it.

Mr. HOWE thought that the Government should regard the interest of the many in dealing with the conflicting and selfish associations that stood in the way of all these improvements. The object to be aimed at was not to establish a gas company or a water company for those who could afford to pay for such things, but to provide for the mass of the operative population those requisites to health of which they had hitherto been deprived. Those who would be the real friends of the working classes must grapple with the difficulties that might be opposed to this measure—a measure which would be the truest economy if it contributed to keep the mass of the people in health—(Hear). The principle of unity of controlling authority was of great importance in carrying out in any district the various operations referred to in this bill. If defects existed in corporations, let them be corrected, so as to allow the objects of the measure to be efficiently carried out. But, at all events, let there be a uniform system. The noble lord, if he persevered, could not fail to meet with the success which he deserved.

Mr. BROTHERTON thought there were many difficulties in the way, but they might be overcome by perseverance. The plan of bestowing certain powers on corporations was a very great improvement.

After a few remarks from Mr. P. HOWARD, Leave was given to bring in the bill.

A handsome silver and breakfast service was presented to Mr. Vidal, of Aveling, on his leaving that neighbourhood, by his patients and friends.

MIDDLESEX HOSPITAL.—At a special general court of the governors of this hospital, a report of the committee appointed to inquire into the government and management of the hospital was read, which stated that the committee, having examined the chaplain and surgeons of other establishments, had come to the decision that the order, discipline, and cleanliness of the hospital by no means equalled that of other metropolitan hospitals; that the nurses were not engaged with sufficient care; that these facts proved the constitution of the weekly board to be defective; the respective offices of matron, and secretary, and house-steward (the last two offices being held by one person), had not been properly filled; that there was a want of cordial co-operation among the officers; that there should be a weekly report as to the management of the hospital; and that Mr. Tuson, one of the surgeons, should resign his appointment. After much discussion, an amendment was carried, resolving, that four copies of the report and two copies of the evidence should lie on the table for the inspection of the governors until that day five weeks, until which time the meeting was adjourned.

The London accoucheurs are amusing themselves with a rather unhappy diagnosis of one of their brethren. The story runs that a distinguished physician was called in to give his assistance in the case of a young lady suffering under a somewhat anomalous enlargement of what women are fond of designating as "the stomach." A careful examination having taken place, a fibrous tumour was "discovered" leeches were applied with characteristic despatch and decision: a few minutes sufficed to show the success that awaits efficient treatment: *the infant* cried!

APOTHECARIES' HALL.—Gentlemen admitted members March 25: James White, Richard Swan Finch, William Lucellos Norris, Henry Nicholson Settle, and T. Armstrong Cammack.

NAVAL MEDICAL APPOINTMENTS.—Surgeons: W. Folds, to the Royal Sovereign; Thomas H. Keown, to the detachment of Marines at Cork. Assistant-Surgeon: Charles B. Wood, to the Caledonia.

MORTALITY TABLE.

For the Week ending Saturday, March 27, 1847.

Causes of Death.	Total.	Average of 5 Winters.

CLINICAL OBSERVATIONS ON SOME OF THE MORE FREQUENT DISEASES OF CHILDREN.

By W. HUGHES WILLIAMS, M.D. (Edin.), Licentiate of the Royal College of Physicians, London; Fellow of the Medical Society, and Member of the Botanical Society of London; Lecturer on Therapeutics and Materia Medica at the Charing Cross Hospital; Physician to the Surrey Dispensary, and to the Royal Infirmary for Children.

GENTLEMEN,—At our last meeting I drew your attention to some guiding principles of diagnosis, with due attention to which, I told you, you would be able to arrive at a knowledge of the general nature of certain maladies under which the sick child might be labouring. I laid more especially stress upon particular points by which your attention might be at once directed to one or other of the great cavities of the body, so far as relates to certain common and acute affections having their seats in these important regions. I also noticed some other signs of a less general character, chiefly, however, to show you how your labours might be lightened by paying attention to such leading principles in endeavouring to arrive at a knowledge of any particular disorder. I shall take up your time to-day with the consideration of one of the most common maladies to which the child is subject—a malady which, wherever and under whatever circumstances you are placed, you cannot help having plenty of examples of it to deal with, not only as a disease, *per se*, as it were, but also as a *diathesis* or condition of body and vital energy which materially influences the course and complications of other disorders under which the patient may be suffering. This disease is *scrofula*, or *struma*.

Any morning that you are here observing the children that come in to us for our consideration, you will not fail to notice that amongst them are several whose complexions are much fairer than the rest, whose irides are of a light hue or bluish colour, whose pupils are often rather dilated, whose hair is the reverse of being dark, and whose upper lip is long, very often everted and swollen besides. All these circumstances are sufficiently prominent to strike you before the mother begins her history of any special complaint—before you know, in fact, for what particular disorder the patient is brought to you for treatment.

On attending to these children you will find, perhaps, that they have eczematous eruptions on the scalp or behind the ears, or are troubled with otitis and discharge from the external passage of the ear, with inflammation of the conjunctiva or the tarsal edges, accompanied with *photophobia*, in other words, great intolerance of light, or with inflammation of the entrance of the nostrils, and scabby incrustations there; or

they may be free from these, but have the submaxillary, or cervical, or other lymphatic glands enlarged or inflamed to various degrees and amounts of intensity. If you examine these children more narrowly still, you will generally discover that the extremities of the long bones are large and appear swollen, giving a very peculiar *articulated* appearance to the joints into the formation of which they enter; less frequently that the extremities of the fingers are *clubbed*, or enlarged and flattened, and that in extreme cases, inflammatory action of a peculiar character is going on round the proximate clubbed margins of the nails. In other cases, the abdomen is enlarged, or the patient is *pot-bellied*; or, if the child is a female, there is discharge from the genitals. If you were to step from the physician's room to the surgeon's, you might find children presenting like *artistic* characters labouring under important disease of the knee, hip, or other joints, or of the bones of the spinal column, &c. &c. Now, in these children you see examples of what I may call the open manifestations of scrofulous disorder, in respect to the diseases to which I have alluded; and in the artistic signs I draw a picture of, you have evidences that the body is endowed with the scrofulous diathesis, or that it may sooner or later suffer such or correlated affections as I have just alluded to, although it is free from them at present.

You observe I have made use of two terms, *scrofulous diathesis*, and *scrofulous disorder*, and given you the characters of both. The propriety of employing these terms, with the idea that they afford any tangible value distinct one from the other, has been, and still is, doubted. I must differ with this notion, and, although I admit the distinction in practice is more artificial than natural, yet it is of great practical utility notwithstanding. By the scrofulous diathesis we mean simply that there exists a disposition, state, or tendency of body which inclines it to become affected with particular forms of diseased action, regarded by every one as the open manifestations or eruptions of disease, and we believe that this tendency or peculiarity of vital endowment is signified to the careful observer by certain physical signs often long before such open manifestations and eruptions make their appearance. This appearance is scrofulous disorder or disease. It is true that the physical signs or artistic characters depend for their existence upon particular structural conformations which must have a cause; and to this, if we generalized still further, the term *diathesis* in one sense might be applied. And in practice it is constantly necessary to generalize thus far, and subject a child to the principles of preventive therapeutics and hygiene whenever he presents such artistic characters, because we know what they indicate, we know what they point to, and, unless infinite care is taken, we shall soon see

the open manifestations of the disorder. But since too often the child is not brought to us under such circumstances, as to all ordinary appearance he eats, drinks, sleeps, runs about, and appears quite well, and is by its parents not thought labouring under any disorder, we have not this opportunity, and we are forced, by the views of society and general opinion, not to regard it as yet the victim of *scrofulous disease*. When we have, on the other hand, the physical education and the whole hygiene of such a child placed at our disposal, we are often enabled to guide it through its future career so successfully that never once shall it betray signs of open disorder. From what I have told you, you find that I believe in the existence of particular signs, such as fair skin, light eyes, &c. &c., as indicative of the tendency to important maladies, and as existing and evincing that tendency before, in generally accepted language, we can say that a scrofulous malady exists. I believe this notwithstanding what has been said, in past times and within the last few months, against it, and that my experience here fully warrants me in so doing. I should tell you that upon this subject, *scrofula*, we have lately had several books published, and in some of these works particular doctrines have been taught which are contrary to those I hold myself and wish to teach you. You know, perhaps, that, years ago, it was said that fair persons such as I have spoken of are not the victims of this disorder; any more than persons of dark complexion are and that in this, as well as in other climates there are no more *artistic* characters evincing liability to the ravages of this disease.

What may be the characters of scrofulous persons in other climates I do not here pretend to tell you, but I must maintain that, whenever anywhere amongst us you find the characters have already spoken to you about, you may depend upon it the patient exhibiting them is liable to that train of maladies called scrofulous disease; and that you may be sure of this, even though, contrary to Mr. Phillips's opinion, the glands be not as yet enlarged. I of course willingly admit that scrofula constantly makes its appearance in children of a complexion, &c. quite opposite to fair, in fact, that it appears in others, presenting all casts and characters; but the point I wish to impress upon you is, that when you see a fair light-haired child, with bluish or light-hued irides, and perhaps a dilated pupil, with large, swollen, everted upper lip, you may with certainty be assured that that child is strumous, and I am certain that at this infirmity the scrofulous children are more often fair than dark. For various opinions upon this point must refer you to the writings of Legol, Philip and Glover. If you refer to some books you will find a host of maladies, all called scrofula, examples of scrofulous disease; and there can be no doubt but that plenty of such maladies exist

but I am not one of those who regard almost every disease occurring in an individual undoubtedly scrofulous as necessary examples of scrofula. Some writers have classed together the most opposite diseases as examples of scrofula, simply because they have occurred in persons who were of the scrofulous diathesis. We cannot deny that this state of vital tendency modifies most materially the symptoms of a large proportion of the diseases to which the frame is subject; but I do not believe we can assent to the propositions that "in persons of this diathesis every disease assumes more or less of a scrofulous nature." I rather incline with the doctrine, that various diseases and healthy inflammation, showing no unusual or specific character, may, under certain degrees of excitement, exist in persons of a decidedly scrofulous constitution. It is undoubtedly of the utmost importance to be aware of the modifications which the scrofulous diathesis induces in other affections, both as relate to their pathology and therapeutics; but it rather falls under a review of these affections to consider them; than to discuss them now as special forms of scrofulous disorder.

Admitting that scrofula occurs in persons the opposite of the fair variety of our race, and also that in certain cases of dark complexion, &c., we have artistic signs of great value as we have in the fair, yet I think you will find that the fair and the dark labour under, as a general rule, different manifestations of scrofulous disorder; or, in other words, the fair variety is more liable to the scrofulous affections of the bones and joints; diseases of the glands; diseases of the skin, such as chronic eczema; impetigo eczematosa; impetigo sparsa; chronic scrofulous ozæna; chronic conjunctivitis; whilst the dark variety is more subject—mind, I refer to children—to general tuberculosis, pulmonary phthisis, chronic abscesses, &c. &c.

Now you will find, from referring to the table before you, that I have opened a very important subject for your consideration, in placing down *pulmonary phthisis*, in fact, *general tuberculosis*, as examples of scrofulous disorder. You all know, of course, that the essential lesional disturbance (so far as the scalpel can make it known to us) of pulmonary consumption is the deposit of a peculiar morbid product called *tubercle*. Now, many persons believe that scrofulous disorder and the deposit of tubercles are synonymous; that tuberculous deposit occurring in a patient is proof he is scrofulous, in fact, that it is a manifestation of scrofula. Some go so far even as to say that scrofula cannot exist as an evident disease without this deposit occurring somewhere. Whether scrofula and tubercular diseases are identical has afforded very lately much food for discussion, some denying their identity altogether; Mr. Phillips even goes so far as to say, that they actually antagonize each other. I cannot here enter upon the arguments of this question, and it will be sufficient for my purpose to give you the results of my reading and practical experience on the point.

1. In a scrofulous individual there is a morbid state of the blood; and one of the most usual tendencies of such a state of circulating fluid is, that during the nutrition of organs, &c., or what is called by physiologists, the organic assimilation of tissues, *tubercle*, as a perversion of such act, shall be formed.

2. It is equally a law attendant upon this condition of blood that inflammation of a specific or peculiar character, often proceeding to exudation, to suppuration, or ulceration, is very liable to attack particular portions of the body.

Now, you will observe that I make both a specific inflammation and the deposit of tubercle the evidences of scrofulous disease—in short, that they are the disease. What I would now particularly impress upon you is, that this tendency to deposit tubercle in a scrofulous person may in many cases never be consummated by its actual deposit, and that the occurrence of the specific or scrofulous inflammation, &c., in various parts of the body, producing, however, disorder which may be even fatal, alone constitutes in many

persons the disease. Thus, you will find children suffering under scrofulous conjunctivitis, otitis, lymphadenitis, disease of the bones and joints, in whom you have no evidence that deposit of a specific character has as yet ensued, and yet these children may be, if I am allowed the expression, *saturated with scrofula*. It is true that sooner or later, after inflammation of a scrofulous character has been going on in the glands and bones, deposits are found; but this inflammation may exist to a certain extent without them, and, when the latter are found, it is very doubtful in my mind whether the "yellow lardaceous deposit" of the cancellated tissue of the bones, and certain other deposits, are really tubercles or not. Many persons have examined the "cheesy matter" of the lymphatic glands, the "yellow lardaceous deposit" of the bones, under the microscope, and say that it is impossible to find any essential mark of difference between them and the tuberculous matter of the lungs. Be this as it may, it is not necessary, in my opinion, for the establishment of the existence of scrofulous inflammation, that it should be proved to be either followed or preceded by deposit of a specific character. Whenever scrofula is openly manifested as a disease, we must have either one or other of two things going on: we may have, or have had, or shall have, both, viz., inflammation presenting peculiarity of form and results, or the deposit of tubercular matter; the former may take place without the latter, and the latter without necessarily being preceded by the former—at least, in my opinion.

It is probable—I have stated my belief elsewhere, in other words, that it is so—that in different constitutions the disposition, more particularly either to the inflammatory forms or to the tuberculous, exists, whilst in others they may both run together. But that the two are antagonistic, instead of being different manifestations of the same general diathesis and constitution of body, is a view of the question I most entirely abrogate.

In allusion to the tuberculous forms of scrofulous disorder, there is a point of great interest and importance, in my mind, and to which I would direct your attention for a moment. It is to a means of diagnosis I refer—a means I have nowhere read about, nor did I hear anything of it until I alluded to it one evening at the London Medical Society, where, although certain statements were made, I heard nothing to warrant me in refusing myself the credit, if there is any, of its first promulgation. It is this: you shall have a child brought to you who has dark irides, no colour in the cheeks, and darkish hair; the eye is often very full and large—looking (to use the words of one of the late house-surgeons of the infirmary, to whom I was talking about the subject) "as if they would eat you;" the eyelashes very long, close together, so long as sometimes to be three or four times their common length: I have seen them so long that when the eye was closed they quite rested on the cheek. Now, if you examine the forehead of such a child, you will find it covered with close-lying hair, sometimes almost down to the eyebrows; if you strip the child you will find its arms covered too, and the back from the hair of the head down between the shoulder-blades quite hairy, the hairs often being very thickly placed, and dark in colour; in fact, the child is quite a hairy child—not quite an Orson, but still very hairy. Often indeed the whole appearance of the patient is cachectic as well. Now, in nine cases out of ten, such a child is tuberculous, it either has tubercles already deposited, or else is liable, is tending to it, and that perhaps in almost every organ of the body, and in the lungs especially. This hairy condition in a cachectic or unhealthy-looking child is a sign, generally speaking, of a constitution miserable in the extreme—saturated with scrofula.

Sometimes you will find this hairy condition in rather light-haired children too; I do not mean the very fair ones, but still not the dark; and then the hair has the peculiarly rough, scrubby, unglossy, dry, or harsh character you

so often find that it has in light-haired girls or young men in the more advanced stage of pulmonary consumption.

DUMAS ON ORGANIC CHEMISTRY. No. XVII.

ON THE URINE.

(Continued from p. 112.)

Calculi in Animals.—Animals of most kinds are subject to calculi. In cats we have found concretions of phosphate of lime and of the ammonio-magnesian phosphate. In the urinary calculi of dogs we not uncommonly meet with uric acid, earthy phosphates, oxalate of lime, and even cystine. M. Jassaigne analysed the calculus of a dog, which contained 97.5 of cystine and 2.5 of phosphate or oxalate of lime. In rats we very often discover calculi formed of a mixture of carbonate of lime and of the phosphate or oxalate of lime. The calculi met with in the herbivora are formed of the phosphates, invariably mixed with a more or less considerable quantity of carbonate of lime. Frequently even this latter salt constitutes almost the entire stone. Klaproth analysed a calculus found in a large sturgeon: it contained, besides phosphate of lime, traces of sulphate of lime, and a little albumen.

In the treatment of urinary calculi, various chemical means have been employed: such as dissolvents, &c., whether taken internally, or injected immediately into the bladder. But, if we bear in mind the complex structure of certain calculi and the varied nature of the materials which enter into their composition, we may readily conceive that the same dissolvent will not suit all cases. The concretions formed of uric acid or the urates will require the employment of alkaline solutions; whilst those which are formed of the earthy phosphates can be dissolved only by acid liquors. Hence, the necessity of knowing the nature of the calculus before adopting the treatment. The composition of the urine itself will form our guide in this research. Where phosphatic deposits exist, the urine will most probably be habitually alkaline; whilst the acidity of this liquor would rather be an index in favour of the existence of the uric calculus.

Where we have to dissolve a calculus formed of earthy phosphates, it has been proposed to inject into the bladder a very dilute solution of nitric or hydrochloric acid. We must, however, acknowledge that this practice is inefficacious in the majority of cases, and frequently even dangerous. We have still less chance of success where we endeavour to administer acids internally. We know, in fact, that the mineral acids do not pass into the urine, and that the organic acids are invariably decomposed in the economy. The administration of alkaline liquors, as, for instance, dilute solutions of carbonate or bicarbonate of soda, or even borax, have been long recommended for the purpose of dissolving calculi formed of uric acid. The Vichy waters have, according to some physicians, offered great advantages in the treatment of calculus; others, however, have altogether denied their benefit. Yet it appears that these concretions have sometimes become less coherent and more friable under the use of these waters.

Alkaline solutions may be especially employed as a prophylactic means. Not only do they dissolve the excess of uric acid, which has a tendency to become formed in the economy, but, also, they probably prevent its formation.

While discussing the causes of animal heat, we showed that it was by the intervention of bases that the phenomena of combustion were accomplished in the economy, and that products which otherwise would be incapable of absorbing oxygen, completely remove it from the air under the influence of these bases. In the treatment of uric-acid gravel, the bases act, then, either by dissolving a portion of this acid, or by preventing the transformation of the azotized materials of the economy into uric acid by effecting a more advanced combustion which transforms

them into urea. We must bear in mind, however, that by rendering the urine alkaline, we run a risk of favouring generally the production of acids, and consequently that of uric acid itself. M. Prunello even states this to be the effect of the Vichy waters; but my own observations incline me to think the contrary.

From the action which the alkalis exercise over normal acid urine, some have been led to conclude that the use of Vichy water or that of carbonate of soda might give rise to the formation of calculi of the earthy phosphates. But is this fear well founded? If the urine be secreted by the kidney with an alkaline reaction, whence come the phosphates, and why should they be deposited in the bladder?

An exciting regimen greatly favours the formation of uric-acid calculi. We may readily understand how it is that too succulent a diet, by introducing into the economy an excess of azotized matters, will give rise to the formation of a large quantity of uric acid. To this we must add, that the abuse of alcoholic drinks and fatty aliments will also favour the production of this acid, by preventing the complete oxidation of the azotized materials of the blood. By an analogous reason, sedentary occupations predispose to the formation of uric-acid calculi. It has been found with some patients, after their quitting town, and pursuing a more active kind of life in the country, that uric acid had ceased to be deposited in the bladder, and had given place to oxalate of lime. Uric acid may, undoubtedly, under the influence of an excess of oxygen, become transformed into urea and into oxalic acid. If the respiration, and consequently the absorption of oxygen, be still more active, the oxalic acid will in its turn disappear to become converted into carbonic acid. However, with regard to the calculi of oxalate of lime, we generally admit that their formation is due to oxalic acid or to the oxalates arising from the aliments. We have, in fact, seen that these bodies may pass into the urine. Persons who are subject to these calculi should, consequently, abstain from taking, as aliments, plants which, like the sorrel, contain oxalates.

URINE OF ANIMALS.—Mammiferous Carnivora.—The composition of the urine in the mammiferous carnivora greatly resembles that of man himself, in regard to the nature of the bodies which are found in it; in general, however, it contains less water, and is therefore of a denser character. According to Vauquelin, the urine of the lion and of the tiger is alkaline; it contains neither phosphates nor uric acid. Hieronymi, on the contrary, states that the urine of these animals is transparent, of a clear yellow colour; its odour is strong and disagreeable; its taste bitter and nauseous; it manifests an acid reaction, which after a short time disappears, to give place to an alkaline condition, due to the disengagement of ammonia. Its specific gravity varies from 1.069 to 1.076. It gives on analysis:

Water	816.1
Urea, alcoholic extract, and lactic acid	132.2
Uric acid	0.22
Mucus	5.1
Sulphate of potass	1.2
Sal ammoniac, with a little chloride of sodium	1.16
Earthy phosphates	1.76
Phosphates of potass and soda	8.02
Phosphate of ammonia	1.02
Lactate of potass	3.30
	153.98 1000.0

Mammiferous Herbivora.—The urine of the herbivora in like manner contains urea, although in much less quantity; but, in place of uric, we here find hippuric acid. What, however, essentially distinguishes this from the urine of man, is that it normally presents an alkaline reaction.

Horse.—The urine of the horse has been recently analysed by M. De Bibra. It was alkaline, and, after a few minutes, deposited a

yellowish-white matter, principally formed of carbonates of lime and magnesia. The mean density of this urine ranged about 1.045, and the quantity of solid matter varied in it from 12.5 to 8.5 per cent.; the hippuric acid in like manner fluctuated between 1.5 and 0.5 per cent. It contained:—

	I.	II.
Water	885.09	912.84
Extractive matter soluble in water	21.32	19.25
" in alcohol	25.50	18.26
Salts soluble in water	23.40	40.00
Salts insoluble in water	17.80	
Urea	12.14	8.36
Hippuric acid	12.60	1.23
Mucus	0.05	0.06
	1000.00	1000.00

The saline residue contained, besides earthy carbonates, from 40 to 50 per cent. of alkaline carbonates. M. Bibra did not observe the generally acknowledged fact, that the hippuric acid contained in the urine of the horse, while in a state of rest, is during work replaced by benzoate of ammonia.

M. Boussingault analysed the urine of a horse fed on green trefol and on oats; he found in it:—

Urea	31.00
Hippurate of potass	4.71
Lactate of potass	11.28
Bicarbonate of potass	15.50
Lactate of soda	5.81
Carbonate of lime	10.81
Carbonate of magnesia	4.16
Sulphate of potass	1.18
Chloride of sodium	0.71
Silica	0.01
Phosphates	0.00
Water and undetermined matters	910.76
	1000.00

Diabetic Horse.—The following were two analyses of the urine in a diabetic horse, made by MM. John and Lassaigne:—

	John.	Lassaigne.
Water	948.50	980.0
Aqueous and alcoholic extract	33.30	
Urea	33.30	
Mucus, with a little carbonate of lime	0.60	15.0
Hippuric acid	1.40	
Chloride of potassium	traces	
Urates of lime and potass	0.11	
Phosphate of lime	0.70	
Carbonates of lime and magnesia	3.92	
Oxides of iron and of manganese	traces	
Sulphates, alkaline phosphates, and chlorides	11.10	
Sulphate of potass	00.00	5.0
	1000.00	1000.0

The Ox.—The urine of the ox has been analysed by Sprengel, who found in it:—

Water	928.2
Urea	10.00
Albumen	0.10
Mucus	1.00
Benzoic acid	0.00
Lactic acid	5.16
Carbonic acid	2.50
Potass	6.61
Soda	5.51
Silica	0.36
Alumina	0.01
Oxide of manganese	0.01
Lime	0.65
Magnesia	0.36
Chlorine	2.72
Sulphuric acid	4.05
Phosphorus	0.70
	1000.00

M. Bibra has given us a more recent analysis of the urine of the ox. It is as follows:—

	I.	II.
Water	912.01	923.10
Extractive matters soluble in water	22.48	19.43
Matters insoluble in alcohol	14.21	10.30
Salts soluble in water	24.42	25.77
Insoluble salts	1.50	2.22
Urea	19.78	10.22
Hippuric acid	3.55	12.00
Mucus	0.07	0.06
	1000.00	1000.00

We are indebted to M. Boussingault for a perfect analysis of the urine of a cow, which had been fed on after-grass and potatoes. The following were the results he obtained:—

Urea	18.48
Hippurate of potass	16.51
Lactate of potass	17.16
Bicarbonate of potass	16.12
Carbonate of magnesia	4.71
Carbonate of lime	0.55
Sulphate of potass	3.60
Chloride of sodium	1.52
Silica	traces
Phosphoric acid	0.00
Water and undetermined matters	921.00
	1000.00

The saline residue contained 77 per cent. of carbonate of potass.

Goat.—The urine of the goat is limpid, of a peculiar, penetrating odour, having a density of about 1.008 or 1.009, and possesses, like the foregoing, an alkaline reaction. According to M. Bibra it contains:—

	I.	II.
Water	980.07	983.99
Extractive matters soluble in water	1.00	0.58
Extractive matters soluble in alcohol	4.51	4
Salts soluble in water	0.80	0.40
Urea	3.78	0.76
Hippuric acid	1.25	0.88
Mucus	0.06	0.05
	1000.00	1000.00

100 parts of saline residue contained 53 parts of carbonate of soda.

Camel.—The urine of the camel has been analysed by Professor Brande: 95 parts of this liquid contained:—

Water	75
Phosphate of lime	
Sal ammoniac	6
Sulphate of potass	
Urate of potass	
Chloride of sodium	8
Urea	6
	95

M. Chevreul, to whom we also owe an analysis of this urine, discovered in it neither uric acid nor any of the phosphatic salts. He found it very rich in urea, and he further proved the presence of carbonate of lime, carbonate of magnesia, sulphate of potass, chloride of potassium, carbonate of potass, chloride of sodium, hippurate of soda, carbonate of soda, sulphate of soda, and some traces of oxide of iron.

Pig.—M. Boussingault has recently published some detailed analyses of the urine of a pig fed on potatoes. In 1000 parts of this liquid he found:—

Urea	4.90
Bicarbonate of potass	10.74
Carbonate of magnesia	0.87
Carbonate of lime	traces
Sulphate of potass	1.98
Phosphate of potass	1.02
Chloride of sodium	1.28
Alkaline lactate	undetermined
Hippuric acid	0.00
Silica	0.07
Water and undetermined organic matters	979.14
	1000.00

of the operation, was quite unconscious of any operation having been attempted. Indeed, her first expression was—"Give me some more ether, that I may have the operation performed now." After being fully aroused, she assured us she had felt nothing, and was most thankful to be assured that it was all over; and well she might, for, on examination, there was no doubt as to the malignant character of the tumours. Every symptom since the operation has been most satisfactory.

On the first application of the knife, the patient moved her body a little, which those unacquainted with such cases, and similar automatic or reflex actions during the primary stages of hypnotism, might naturally enough have mistaken for emotional manifestations, or indications of the patient suffering pain at the moment, although not remembered after she awoke. The movement in question, however, was only *spinal* or *reflex*, and was manifested in the same manner at the same stage of the etherization, at every one of my experimental trials, when there was no source of irritation to the spinal nerves, unless what arose from the laboured breathing of the patient. When consciousness and volition become impaired or suspended, reflex movements become more easily excited, as was the case in the present instance; but, had we carried it further, so as to have torpified the spinal function, we should have been certain to have had no muscular indication whatever; but such condition is not always free from danger, as recent experience has proved. I, therefore, consider it much more prudent to run the hazard of exciting automatic indications of pain, but which are not attended with positive feeling of pain, than to push the process so far as to be certain to prevent present appearance of suffering, but which may issue in the most grave or even speedily fatal consequences after the operation.

There is one other caution which I wish to advert to, as it appears to me to be one of great importance, whilst, at the same time, so far as known to me, it has not yet been formally adverted to by any of the numerous writers who have shed so much ink on the ether question. I refer to the moral abuse to which ethereal narcotism is capable of being turned by cruel and unprincipled individuals. Much has been said and written on this point against *mesmerism* by dogmatic sceptics and unscrupulous fanatic opponents of *mesmerism*; but no such allegations have been made to the prejudice of the indiscriminate use of the narcotizing fumes of ether. Now, nothing can more clearly demonstrate the power of prejudice in rendering its victims incompetent observers, or un candid reasoners on facts brought before them, than this conduct of the opponents of *mesmerism* and *hypnotism* on this important point. It would naturally be supposed by those unacquainted with the facts of the case, and who have read the lucubrations of some of the anti-*mesmerists*, that the former methods were directly calculated to excite the animal passions in an uncontrollable degree, and that unfortunate and virtuous females might be victimized by designing and unprincipled men, even without their consciousness of the fact when restored to the waking state, or their possessing any mode of bringing home to the unscrupulous culprits a charge of their villany. I say all this we are led by such individuals to infer as a just source of charge against *mesmerism*, whilst there is not a whisper against the use of ether, as liable to be converted to such unholy purposes. Now, what are the facts? Why, quite the contrary. I am bound in candour to say, from my experience of both, that there is far greater danger of ether being converted to such immoral purposes: for, of all the cases I have ever seen hypnotized (my mode of *mesmerizing*), I have never seen a patient whilst in the second conscious state who was not more tenacious of resisting any apparent attempt at taking a liberty with her, either in the way of asking her to take off a shawl, or neckerchief, or stocking, or to give a kiss to a gentleman (this may be an imaginary gentleman, suggested as ac-

tually present, and, as in dreaming, they always take suggested ideas for realities), I say I have never yet seen a patient in that state who would not repel such proposed aggression with more energy than in the waking condition. I do not suppose it would make a vicious person virtuous, but I feel confident that *mesmerism* has no direct tendency to make a virtuous person vicious. What might be achieved by systematic and persevering attempts to corrupt a virtuous person during that state, I do not pretend to tell, and should never condescend to be a party to witness such attempts being systematically made, but my present convictions are that the same individual might be more readily demoralized when awake, than when in the second conscious state of nervous sleep, which evidently has a tendency, with virtuous people, to quicken their perceptions and heighten their notions of what would be immoral or highly indecorous, whilst at the same time it renders them most docile and obliging. In all which is reasonable and seemly in their estimation. Thus, while they will indignantly repel the proposal to kiss an imaginary gentleman, they will be quite willing to do so to an imaginary child.

A libidinous manifestation I have never seen during *hypnotism*, but I have witnessed the most intense manifestations of *erotism* arise spontaneously on several occasions during the primary or exciting stage of etherization, and that even in a patient of high respectability, and of the most modest and virtuous conduct, and pious disposition in her general deportment when awake. I beg also to appeal to the answer given to the nurse of the Baron Dubois's patient, lately recorded in your pages, as well as to the fact of her drawing the nurse towards her and kissing the nurse during the process, as cogent proof in support of my opinion on this point. So fully satisfied am I of the fact, that I deem it a duty to call special attention to it, and to recommend the propriety of always having a third party present when etherizing ladies, so as to guard against the possible risk of imputations of criminality being brought against the operator from parties, which might arise in the mind of the patient, and bring disgrace, perhaps undeservedly, against the operator, and excite an invincible prejudice in the public mind against the use of ethereal narcotism, because of its real or supposed abuse (a). I would recommend the same caution in regard to *hypnotism*; as then there can be no room for wicked and malevolent individuals to assail the characters of innocent people with crimes which they allege against others, no doubt from feeling their own vicious propensities and want of moral control are such as would lead them to attempt the perpe-

(a) Besides the possible danger which might really occur to the patient, or the mere dread or suspicion which might take possession of her mind on the point, a danger might arise to the operator in the following manner: A vivid dream might occur during that stage of ethereal narcotism which would render it certain to be forgotten after the patient recovered, but this might recur on a future occasion with all the force of reality, and as the remembrance of a previous fact which had actually taken place; and this latter dream, having occurred at a less intense state of narcotism, might be remembered by the patient on recovering, and be believed and related by her as a fact to the great distress both of herself and other party implicated. It is in this manner that many an innocent person has, during a fit of delirium, inculpated both herself and others, and which those ignorant of the true explanation are ready to set down to the power of an awakened conscience, which would not suffer the person to die without making such disclosures and confessions. When the patients allege they have committed impossible crimes, the true solution may be admitted; but, when possible or probable ones are alleged, they are too frequently set down as facts. It is therefore important to guard against the possibility of the occurrence of such awkward results.

tration of, if placed in similar circumstances. I would beg leave, however, to offer a word of caution to such individuals. Supposing they were placed in the most favourable circumstances for the perpetration of such crimes, and that, by systematic and persevering attempts, they had at length achieved their purpose, and that, on awaking, the patient had no remembrance whatever of the injury inflicted on her, and that there was none but the eye of Heaven to witness against them, let them not indulge in the delusive hope that they could not possibly be inculpated. From the well-established and most beneficent law of double consciousness, it is quite certain that, however completely the transactions which occurred during the sleep may be forgotten, on awaking, she has only to be hypnotized or *mesmerized*, when put into the witness-box, to render her as competent to give accurate testimony of all which occurred in her former state of nervous sleep, as in the waking state she could testify to facts which occurred in her waking condition. Now, I maintain there is not a like security for the person who might be victimized during ethereal narcotism. By this means patients might be rendered speedily entirely oblivious of what was occurring, and that without the benefit and security of the double-conscious memory to be summoned to the conviction of the perpetrators of their wrongs. The most judicious mode, however, is always to etherize or hypnotize females whilst a third party is present, as then all quibbles will be guarded against of ether being abused and turned to immoral purposes.

In conclusion, I beg leave to urge in the most earnest manner:—

1. That no important surgical operation should be attempted under ethereal narcotism without one or more preparatory experimental trials having been made prior to the day of operation.
2. That well washed and purified ether alone should be used for such purposes.
3. That the air breathed at first trials should always have a moderate charge of ether vapour, either by the temperature of the air being regulated, or the apparatus provided with double-working valves, so as to regulate the proportion of ether, the strength of which to be gradually increased, so that the proper strength and quantity should be determined on for each individual case prior to the day of operation.
4. That when any circumstance may render it necessary to perform the operation without delay, it should rather be done with the risk of slight manifestation of pain to the patient, than be carried so far as to endanger his ultimate safety.
5. That the tubes and valves of the inhaling apparatus should be sufficiently large and easy in their action to permit the respiration to be carried on with the least interruption possible.
6. That the nostrils should not be stopped for the few first respirations, so that the respiratory organs may become tolerant of the etherized air at a low charge, before being inhaled at what may be considered sufficiently strong for fully narcotizing the patient; and, when the respiratory organs are very irritable, a slight admixture of watery vapour should be used, as recommended by Mr. Startin.
7. That etherization should never be attempted in the case of females, without the presence of a third party.
8. That in no case should the narcotizing influence be carried, immediately preparatory to the operation, beyond that stage which previous trials have proved are readily recovered from.
9. That in protracted operations the patient should be caused to breathe a less concentrated form of the vapour after the first incisions; or made to breathe pure air and etherized air alternately, in such proportions as may seem requisite to keep the patient slightly under its influence, but carefully guarding against inducing such degree of collapse as may seriously interfere with the function of respiration; as, if that becomes seriously depressed, we have no cer-

tain means of rousing the patient and removing the impending danger, as it is through the lungs chiefly that the ether is eliminated from the blood.

10. That an operation should never be undertaken when the patient is only partially etherized, and still capable of feeling acute pain, as in such condition with many patients, the pain and emotion and shock to the nervous system are likely to be greater than if they were in the natural state (a).

I think the above precautions embody all which is essentially requisite for the safe and efficient use of ether in surgical practice, according to my own experience and the recorded opinions of others which have fallen under my notice; and, with a due regard to these precautions, we need not fear that its use will be as hastily proscribed as it was at first zealously adopted.

I quite concur in the opinion, so well expressed by you in your last week's leading article, when you say, "It is our privilege to contend that ether, while it is neither so magical nor safe as some zealots would describe it, possesses in prudent and enlightened hands clear and incontestable advantages which should for ever attach it to medicine as one of its most valuable and precious adjuvants. It is not, nor ought it ever to have been supposed, an agent without danger under all circumstances. It is a law of nature, that whatever is greatly valuable in its use must be proportionately mischievous in its abuse; and it is impossible to survey the powerful effects of ether on the human frame—producing a total revolution in the whole physical and, we may add, psychical system of the patient—without feeling that the extremity of beneficial influence beneath our eyes must be lying very near the confines of that power which wields the sceptre of lethal disease and death. But it is the distinction of the true physician that out of the nettle danger he plucks the flower safety—that he can advance to the very boundaries of peril to secure the elements of conservation; and that, though the right path be narrow, his knowledge and skill enable him to walk it with as much certainty and assurance as though it were the broadest and safest highway."

3, St. Peter's-square, Manchester, March 26.

OBSERVATIONS ON THE ACTION OF MERCURY IN INFLAMMATION, AND ITS EFFECTS ON THE SYSTEM.

By HENRY SMITH, M.B.C.S.,

Late House-surgeon to King's College Hospital.

In the beginning of the year 1845 I read before the Medical Society of King's College a paper in which I endeavoured to prove that mercury acts beneficially in inflammation by becoming absorbed into the blood, and altering the quality of its constituents. The additional experience of two years' study of diseases, and the effects of this remedy, has enabled me to strengthen my observations, and to put my ideas together in a more clear and satisfactory manner to myself; and I now lay them before the readers of the *Medical Times* with a hope that they may not prove uninteresting to those who are willing, like myself, to add their share, however small, with the view of advancing our knowledge, and rendering our profession more of a science.

Of all the remedies which are employed in the treatment of disease no one has been so much abused as mercury. A weapon of immense power and usefulness, it has too often, when wielded by the unskilful, careless, and unscrupulous, become one of injury and destruction. It is so much employed, and so universally admitted to be one of our most powerful therapeutical agents, that much has been written about it, and many experiments have been made by

(a) I strongly suspect that the fatal result of the Grantham case arose from this cause—not from too much of the ether, but from too little being used, when used at all.

careful and eminent observers, with a view to determine its precise mode of action, and to find some satisfactory explanation for the symptoms which it produces; and although theories have been propounded, and no satisfactory conclusions have been obtained, nevertheless much benefit has resulted from these inquiries, inasmuch as the nature of the remedy itself, and its good or evil effects, have become more clearly understood, and more caution has been used in its employment; and this mineral, which may well be said to have been rendered by man a curse to mankind, is now found to be most efficacious in restoring him to the most inestimable blessing, health. Thus we seldom see the disastrous consequences of mercury, as were daily noticed before the time, and even after the time, of John Hunter; who was the chief means of bringing about a revolution in its employment in the treatment of the venereal disease.

These sad mistakes occurred in consequence of an erroneous opinion being entertained as to its action. It was thought that it acted chiefly through the salivary secretion, and drove out at that point the morbid poison; it was, therefore, given to such an extent that profuse salivations were brought about; and, until this effect was produced, it was not considered that the disease was sufficiently overcome; to use the words of John Hunter, "Normally, where the management of mercury was not so well understood, nor its effects in syphilis well known, it was generally supposed to act by evacuation from the salivary glands, and was, therefore, always given till that evacuation took place; and, as its effects in the cure were imagined to be in proportion to the quantity of this evacuation, it was pushed on as far as possible without endangering suffocation."

At the time John Hunter made these observations, mercury was used in no other complaint but that of the venereal disease; therefore his inquiries were made principally with a view to determine its mode of action in that disease alone; nevertheless his observations will be found to bear upon the point I am going to consider, namely, its action in inflammation. Before, however, proceeding to this I will first review the effects produced by it on the healthy body.

When taken in moderate doses, it increases the action of the various secreting glands and organs, and stimulates some in a particular manner. Thus its powerful action on the salivary glands is perceptible to the senses, and from this fact we may have reason to believe that a somewhat similar influence is exerted upon the remainder of the secreting glands and organs; we are certain that the liver is stimulated to an increased secretion of bile, as is noticed after mercurial purges have been given, when there has been a suspended secretion of bile; this fact is best exemplified in a disease in which the liver, not primarily, but secondarily, is in fault, namely, cholera. In this disease profuse watery discharges, deprived of bile, occur. After the exhibition of large doses of calomel, a considerable flow of bile is observed to take place, and the symptoms are relieved.

Mercury directly increases the secretions of the intestines, independently of its action on the liver, and thus it acts in two ways in producing evacuations from the bowels.

Thus, then, we see that mercury acts chiefly on the different secreting apparatus of the body; and it proves beneficial in this way in a variety of disorders, and becomes a valuable medicine. But is this its only mode of action? Does mercury have the powerful effect of overcoming inflammation, and of causing the removal of materials deposited from the blood, by increasing the secretions of the various tissues only? Is this an adequate explanation of its salutary effects? By no means: we must go further, and seek some other view of the matter; and, in order to do this properly, we must first sketch the phenomena of inflammation.

The chief characteristics of inflammation are, that the relative quantity of the constituents of

the blood is altered, and that these constituents are thrown out as abnormal products. The fibrine is increased in quantity, and it is the fibrine that is thrown out in the shape of lymph. Serum also is thrown out, and it is found to be richer in albumen. As regards the state of the vessels themselves engaged in this process, it has been pretty accurately determined that they are enlarged and relaxed, and allow a larger quantity of blood to accumulate in them. The nervous system is much disordered when there is any severe attack of inflammation. Now, let us inquire how it is, mercury produces its beneficial effects; but, first, let us look at some of the theories which have been entertained on this point.

From the fact of the vessels being enlarged and dilated in inflammation, it has been considered that those remedies which do good in this state produce quite the opposite condition, namely, contraction, whereby accumulation of blood, and the results of this accumulation, are overcome; amongst these mercury is placed. But how can we explain the various phenomena following upon the administration of mercury by this hypothesis? Will mere action on the vessels themselves be sufficient to produce salivation; the great disturbance of the system, the great tendency to gangrene, and the change in the blood itself, which we will presently see takes place under the influence of mercury? We must go further, I think, and seek in the blood itself for an explanation of these effects.

Nevertheless, although I do not think that mercury acts as an antiphlogistic by acting on the vessels, there can be no doubt that a diminution of their calibre takes place after any treatment calculated to overcome inflammation. Thus, bleeding will produce this effect; because, the quantity of blood itself will be diminished in the part. Tartar emetic will probably have the same effect, but not directly, by any constricting or stimulating action on the vessels, but by depressing the action of the heart, and thus preventing an increased flux of blood to the part. Mercury also, by overcoming inflammation, brings about a contraction of the vessels; but that this is produced through some other means than mere action on the vessels, I shall endeavour to show directly.

Again, it has been supposed that mercury acts by producing an impression upon the nerves. Mr. Swan, who holds this view, has made many experiments on the lower animals, which have caused him to come to this conclusion. After injecting mercury into the veins of these animals, and administering it to them in other ways, he found that the nerves of the ganglionic system were highly inflamed, and he ascertained that there was a similar state of these nerves in a man whom he dissected; from this fact, and from the circumstance that his face and mouth appeared much swollen, he comes to the conclusion, without knowing it for certain, that the man had been salivated previous to his death. In these experiments it is probable that the appearance of the nerves, noticed, was produced by the mercury; but, even if such is the case, we are not warranted in believing that its mode of action is through this channel, and this alone. Mr. Swan, in an ingenious manner, even attempts to account for the salivation, by inflammation and irritation being propagated to the salivary glands, through the nervous twigs which are distributed to them. I am afraid little reliance can be placed on this gentleman's experiments; as such a large amount of mercury was given, and such a state of poisoning produced, that one would not be surprised to find inflammation anywhere. We know well that, when mercury has been given to a large and intense amount, inflammation may be excited in various parts of the body. The skin, mucous membranes, periosteum, cartilages, and bones, are all attacked, and inflammation is produced; but, because this is the fact, we do not conclude that mercury acts beneficially, by producing this artificial and abnormal state.

Many are of opinion that mercury acts as a

derivative; there is no doubt that it acts partly in this manner. We see that it produces local inflammation, and greatly increased secretion from various organs; it therefore must necessarily derive from other parts and organs, and act beneficially when they are in a state of inflammation; but these effects are not adequate to explain its full action. If we look to the blood itself, we shall find, I think, a proper explanation; at all events, one much more rational and satisfactory than can be come to from the theories I have detailed. I think that it is *through* the blood, and *upon* the blood, that mercury exerts its powerful and beneficial influence; and it is only by taking this view of the matter that we can explain *all* the phenomena following upon its administration. We have seen the effects of mercury when taken in moderate quantities; let us now inquire into the symptoms which it produces on the system when it has become affected by it. The health of the person gets gradually out of order, a species of poisoning is produced, the animal and organic functions are both greatly interfered with. The body becomes weak and irritable; there is loss of appetite and thirst; emaciation takes place sometimes rapidly. The pulse becomes frequent and feeble; the face thin and pale, and presents a peculiar appearance. There is a great increase in the flow of saliva; and sometimes a profuse secretion from other organs, as the bowels or skin. These are the symptoms perceptible to our senses; but is there any effect on the blood, and, if any, what change is produced? There is found to be a change in this fluid; it is altogether of a much less healthy nature; the clot is less solid and more easily broken down, there is less cohesion between the parts which form the vital part of the blood. In some cases it will not show any tendency to coagulate, in others it is found to be thick and tarry. Generally speaking, the blood drawn from a patient under the influence of mercury is buffed and cupped; experiments have been made with a view to determine whether the constituents of the blood have been altered in quantity, and it has been found by M. Andral that the fibrine has somewhat increased. This we should not at first expect to find; but, when we come to consider the febrile state of the system which is produced by large doses of mercury, we are not surprised to find this fact, and I think we may clearly explain it on this alone. Although we may not be aware of the essential change in the blood produced, yet I think we may come to the conclusion, that it acts as a direct poison upon it, and, therefore, exerts an unhealthy influence over it, and impoverishes it; and, in order to illustrate this, let us go further, and inquire into the symptoms of fatal poisoning by mercury. They all indicate an altered state of the blood, and a great want of vitality. There is great irritation and prostration of strength, excessive salivation, ulceration of mucous membranes, and, finally, gangrene. Sometimes there is hemorrhage from the nose and mouth, or hemorrhagic spots under the skin.

We cannot, I think, resist the conviction, that, in order to produce these symptoms, a decided change must take place in the blood itself, independent of any action through vessels or nerves; and it is in this way, by producing this change in the constituents of the blood, that I believe it acts in inflammation. We know that the system must become affected with the remedy before it has any beneficial effect on an inflamed organ; and that a longer or shorter time is necessary before this takes place, as it is more quickly or slowly absorbed; this would not be the case if it acted merely through the nerves, or upon the vessels, for we know that medicines that act sensibly upon the nervous system and on the blood-vessels are by no means a long time in showing their effects. We know that this remedy acts most beneficially in inflammation, by preventing the deposition of solid and fluid substances from the blood, which is richer in fibrine and albumen; and it is by producing a change in the quality, and probably in the quantity, of these constituents, that, in all proba-

bility, mercury acts. We see by the emaciation, loss of appetite, and general weakness produced by this mineral, that it exerts a most powerful and depressing influence over nutrition; and the fibrine and albumen thrown out are the products of the disordered state of the nutritive function in inflammation; and, therefore, we may justly conclude that these constituents are so altered, when they come in contact with mercury, that they are not in a fit state to become the products of inflammation.

Mercury not only acts by preventing the deposition of lymph, but it appears to have the additional power of causing the speedier absorption of abnormal products which have been thrown out; and the results that we observe in practice warrant us to come to this conclusion. How often does the physician observe the beneficial effects of this medicine in pneumonia, when the lung has become solid, by the effusion of fibrine in its parenchymatous structure! Under the influence of mercury, the lung, which has hitherto been almost impervious to air, gradually returns to its healthy function; day by day, air enters it more readily, the morbid sounds are lost, and freedom of breathing is restored; and how does this happen, except by reabsorption of those inflammatory products which have spoiled for a time the texture and function of the lung? How often does the surgeon see the gradual restoration of a joint take place, when it has been crippled by inflammation and its consequences, under a mild and beneficial course of mercury! What satisfactory results he notices to take place in inflammation of the joints of the vertebrae, when products have been thrown out which press upon the nerves as they emerge from their canals, and produce paralysis of the extremities! He finds, after all other measures have been tried, that mercury is, indeed, "the one thing needful."

Notwithstanding, however, we observe these facts, we often in vain attempt by the use of this mineral to produce the absorption of lymph, or serum, which have been deposited, and have existed for some length of time. How often does the physician see that mercury produces no benefit, nor has any power of getting rid of the products which have been deposited upon the valves and lining membrane of the heart, nor of reabsorbing the fluid which has been poured into the cavity of the pleura or abdomen! It is therefore highly probable that mercury causes the removal of these inflammatory products, in many cases, not by any direct stimulating effect upon the absorbents, but by stopping that action which tends to produce effusion. It so alters the qualities of the substances likely to be effused, that this act is prevented. Inflammation, therefore, being overcome, and effusion prevented—the absorbents readily and rapidly take up any material which can be absorbed; and thus it is that we only see the recent products of inflammation got rid of; and why we see no change effected upon those deposits which have existed for any length of time, such as incrustations on the valves of the heart, and chronic collections of serum in the pleura, pericardium, and sac of the peritoneum. And I think a useful practical fact hinges upon this point, as regards the employment of mercury in inflammation. There are some who recommend it to be given only after the acute stage of inflammation has somewhat abated, and effusions have taken place. Thus, for instance, in a case of pneumonia, blood-letting and tartar emetic are recommended in the primary stage, when the inflammation is more severe, and there is more liability of effusion of lymph; but when the lung has become solid we are told to give mercury, in order to produce absorption of the fibrine. But in all cases, "prevention is better than cure." We should recollect that the chief power mercury possesses is its stopping that action which tends to effusion, and not curing that effusion when it has once taken place. The idea, that mercury acts chiefly by promoting absorption, has led to the practice of not giving it directly in inflammatory diseases; this appears to me to be in a considerable degree

faulty and mischievous, as the time is allowed to go by when the remedy may produce its best results. Our object, I think, should be to endeavour to prevent the effusion of lymph and serum, and we shall gain this by giving mercury directly, and thus, as quickly as possible, producing that beneficial change in the quality of the blood which I maintain is necessary for the inflammation to be overcome, and the deposition of these substances to be prevented. Blood-letting and other evacuations should be premised, or used at the same time, as there is no doubt that the system becomes much more easily affected by mercury when these remedies have been previously used; as they tend to diminish that febrile state of the body which exists with all acute inflammations, and which every practitioner knows is inimical to the influence of mercury. There is another fact which, I think, will go far to prove that mercury subdues inflammation, by changing the condition of the blood, namely, that its beneficial effects are noticed mostly in those forms of inflammation where there is a tendency to a deposit of healthy lymph, and not pus or imperfect lymph; and this deposit is found to take place in inflammation of the solid organs of the body and the great serous membranes, excited by common causes, such as wounds or cold. But, on the other hand, when the inflammation of the same parts is caused by some morbid poison circulating in the blood, and therefore unhealthy, the products are of a different nature: the lymph which is thrown out is imperfect, and serous fluids are more or less mixed with pus, and the constitutional fever is generally of a low or typhoid type; and there is a great tendency to further destruction of the tissues by ulceration, suppuration, and mortification. In such cases mercury rarely does good, and then only when it is most carefully given, and combined with such remedies as are calculated to strengthen the energies of the system. In a great majority it will only do harm; as an instance, I may mention the inflammation which attacks the liver. In that form where there is a tendency to a deposit of fibrine, namely, in the cirrhotic, mercury does much good, particularly when given at an early period; but when the inflammation is of that kind which speedily runs on to circumscribed or diffused abscess, mercury will not only do no good, but will tend to aggravate the already existing mischief. Dr. Budd, speaking of the injudicious use of mercury in disease of the liver, says—"There can be no doubt that much of our uncertainty as to the action of this and other medicines arises from our confounding under the same name, and treating in the same manner, diseases different in their nature. It seems to me that mercury is peculiarly unsuited to the disease we have been considering—suppuration of the liver."

Again, in erysipelas and diffused inflammation of the cellular tissue, where no lymph is thrown out, but suppuration and rapid disorganization take place, mercury will fail in doing good, and in many cases will exasperate the disease. The blood is already sufficiently poisoned, and its healthy qualities broken up, to permit a more powerful poison doing any good.

In my next paper I shall speak of the evil results which follow on the administration of mercury.

(To be continued.)

PRACTICAL OBSERVATIONS RELATIVE TO CERTAIN POINTS AT ISSUE BETWEEN TWO OF HER MAJESTY'S COMMISSIONERS IN LUNACY AND THREE NON-MEDICAL GOVERNORS OF THE LINCOLN LUNATIC HOSPITAL.

By WILLIAM SMITH, M.R.C.S.E.
Formerly House-Surgeon to the Lincoln Lunatic Asylum, and to the County Hospital at Lincoln.

"My object is, by every possible effort, to reach the truth; and, if error lie in my way, I must touch it—tear it—trample it under my foot."—ARISTOTLE.

Considerable interest has been excited of late

among those who have turned their attention to the management of hospitals for the insane (myself amongst the number), by a controversy which has taken place between certain members of the Lunacy Commission and a committee comprised of three non-medical governors of the Lincoln Asylum. Having formerly held the responsible office of president medical officer (house-surgeon, as designated by the rules) to that asylum, during a period of three years, and afterwards taken a considerable interest in its management for a further space of more than eighteen months, I may perhaps, without presumption, venture to offer a few remarks on the subject.

That discussions like the present, carried on in our medical journals, have a beneficial interest as regards the welfare of the insane, by removing popular prejudices relative to their supposed ungovernable dispositions and ferocious habits, and thus paving the way for a more humane and enlightened management, no one practically acquainted with the treatment of insanity will deny. In proof of my assertion, I would direct attention to the protracted discussions which took place in the *Lancet* and other medical journals, relative to the humane system of non-restraint, as successfully carried out at Lincoln and Hanwell. To the force of public opinion (directed to the subject through the medium of these journals) the insane are indebted for this and numerous other kindred improvements, notwithstanding the strenuous opposition of parties more studious of their own ease and comfort than the welfare of the patients entrusted to their care, or others, whose hostility was directed against those improvements simply because they did not originate from themselves. It would appear that two of her Majesty's learned commissioners in lunacy inspected the Lincoln Asylum on the 23rd and 21th of September, 1846. They remark, *inter alia*, "We were informed that about fifty patients were employed; that twelve attended the cathedral service on Sundays, and that about sixty are generally present when prayers are read in the hospital. There is no chaplain or clergyman who attends the hospital; but the house-surgeon reads prayers every evening." The three non-medical governors, in their counter-statement, remark:—"Prayers are read every evening by the house-surgeon or matron, and the aid of a chaplain for family prayers is contrary to the general custom of families, and quite unnecessary. It must not be forgotten that the patients belong to various sects of religion, and that some of the patients have been brought to their unhappy condition by fanatical excitement; and that no exclusion of ministers of any particular form of religion could be maintained; all who are in a condition to derive benefit from public worship are encouraged to attend it, and no clergyman in this city would refuse his attendance where it would be useful. The average number attending family prayers is not sixty, as stated by the two visiting commissioners, but ninety-seven, as appears from the weekly return." The governors (to my thinking) commence their argument on false premises, by comparing the asylum to a private family; whereas there must be a wide difference between a public hospital, containing 130 insane persons, and a private family. Moreover, if the Lincoln governors would take the trouble to look around them, they would find that chaplains are thought necessary in most of our best-regulated public asylums, and amongst such, I presume, they wish Lincoln to have a place. At the Surrey Pauper Asylum and at Northampton (I perceive by the annual statements), the chaplain's report is published along with that of the physician: proving the estimation in which the chaplain's services are held in those institutions. The Lincoln governors, in place of referring to a report of the Lancaster Asylum, bearing date so far back as September, 1836, might, with more consistency, have referred their readers to the practice now pursued in our best-regulated public asylums, such as Hanwell, Lancaster, Northampton,

the Royal Hospital of Bethlem, and many others. If "the average number attending family prayers is not sixty, but ninety-seven, as appears from the weekly return," what stronger proof can we require of the necessity of appointing a regular paid chaplain? The county gaol has its paid chaplain, as also the county hospital; the latter contains about sixty beds, whereas the hospital for the insane, containing 130 beds, has no chaplain. With reference to the assertion that "no clergyman in this city would refuse his attendance where it would be useful," I can speak from my own experience (of nearly four years and a half in Lincoln), acquired during my house-surgery at the asylum and the county hospital; that the clergymen of the ancient cathedral city are by no means so zealous in rendering their gratuitous services to the public charities as the governors would lead their readers to infer from proof whereof I would refer to the very irregular manner in which the duties of readers to the county hospital were performed during my stay in Lincoln, whilst under the system of accepting the gratuitous services of those clergymen who offered themselves; and to the still more important fact, that the governors of the county hospital have recently appointed a paid chaplain, proving thereby that the practice of having honorary and unpaid chaplains (or readers) had not been altogether satisfactory. I trust the day is not far distant when the absurd and mischievous practice of having honorary and unpaid physicians and surgeons to our public medical charities will be entirely abolished; when that happy event arrives we may hope to find those honourable posts filled by men of undoubted ability, in place of (in too many instances, I fear) raw inexperienced individuals, whose only recommendation has been the strength of their family connection, or the length of their purse. The commissioners further observe:—"The house-surgeon, or superintendent, is Mr. Walsh, who, however, according to the rules, is not allowed to prescribe for any of the patients, unless an extremely urgent case should occur, and, indeed, he has no share whatever, apparently, in their medical or moral treatment. His time seems chiefly occupied in making up any medicine which the physicians may prescribe (there being, however, very little medicine given); in keeping the various registers prescribed by the Legislature; in superintending the keepers and nurses; and attending the strangers who visit the establishment, and who (as will be seen hereafter) are very numerous." Herein I am of opinion the commissioners have just cause for complaint. What can be a more palpable absurdity than to require from their house-surgeon that he "shall be a member of the College of Surgeons, or of the Company of Apothecaries" (rule 6, section 10), and yet restrict him to the exhibition of salts and senna; and further compel him to accompany through the wards every Johnny Raw who may be prompted by idle curiosity to procure an order for the purpose of staring at the mad folk, actuated, in too many instances, by no higher feeling than would induce him to pay half-a-crown for a peep at Wombwell's menagerie, or to hear the melodies of the American niggers? These are strong remarks, but they result from what I have myself seen and heard whilst accompanying parties of *litterati* through the wards of the Lincoln Asylum. Let me be clearly understood on this point: I do not deny the right of inspection of a public hospital for the insane to the meanest individual in existence; the forlorn beggar in common with the highest peer in the realm "has a deep personal concern in the mild or harsh treatment of a complaint which may affect any, either personally or through relatives and friends." The commissioners remark further on this subject:—"Having adverted to the large number of strangers who are allowed to inspect this establishment, we beg to say that we examined 'The Strangers' Memorandum Book,' in which, according to the rules of the institution, all visitors are required to enter their names, and we found that the number admitted in one month only (August

last), by the orders of governors, amounted to 311. A large proportion of these names were evidently written by uneducated persons; and we were thereby induced to suppose that many of the visits arose from mere curiosity—a supposition which the answers given to our inquiries tended very much to confirm. We think that system of (apparently almost indiscriminate) admission is extremely objectionable." With this opinion I am inclined to concur; and, moreover, a similar opinion, or something even stronger, was entertained by the late Dr. Wm. Cookson and Samuel Hadwon, Esq., a former house-surgeon. I may further observe, that this same indiscriminate admission of strangers called forth some not very favourable comments from Dr. Hitch, at that time the resident medical officer of the Gloucester Asylum, a gentleman whose zeal in the cause of the insane, and general urbanity of manners, has gained for him the highest reputation amongst the superintendents of our best conducted asylums. The unjustifiable and ungenerous plea of the three non-medical governors, "that the only complaints of the visits of strangers have been from some house-surgeon who neglected his duty, and passed half his time out of the house," reminds me somewhat of the practice pursued in our criminal courts, and which is usually termed, in legal parlance, "an Old Bailey plea." An honest cause usually stands or falls by its own merits, and does not require the equivocal support obtained by blackening the characters of the opposing witnesses. I have recently paid a visit to the Lincoln Asylum (April 2), and was informed by the two resident officers, that the number of visitors has greatly diminished of late; perhaps the governors have adopted the plan of their old antagonists, the advocates for mechanical restraint, who opposed the theory of "the humane system of non-restraint" *in uteris*, yet gradually adopted the practice!

The commissioners next observe, "There is essentially no classification whatever amongst the male or female patients. Some distinction is observed as to accommodation between the private and pauper lunatics; but they all meet in the same airing grounds; (the males in one and the females in another), and the quiet and tranquil—the dirty and clean—patients are intermixed; and, during our progress through the house, we heard several complaints, made by female patients, that they were forced to hear blasphemous and obscene expressions, and see violent and indecent acts, emanating from patients in the same ward, from whom they had no power to dissociate themselves. We are disposed to think that the list of injuries and acts of violence which we have set forth in the schedule appended to this report, and which we extracted from 'The Daily Return Book,' is of itself almost sufficient to condemn the system of non-classification that prevails in this establishment." On this head, I am inclined to coincide with the governors in a great measure, if not *in toto*. My object in visiting the Lincoln Asylum, on Friday last (April 2) was to satisfy myself, by personal observation, as to the result of the system which has been so boldly introduced and so firmly defended by the governors at Lincoln. I profess myself to be one of that class "who pin their faith on no man's sleeve"; if any man can strike out an improvement upon an old system, why, I would say, "a God's name" let him do it. It has been a source of much pleasure to me to reflect that the abolition of the depressing influence of solitary confinement was first introduced to the public through my instrumentality, and this, like every other improvement, of course met with considerable opposition. I saw the late experiment at Lincoln as a kindred improvement; in truth, it can only be in asylums of limited extent, like that of Lincoln, that such experiments can safely be ventured upon. The "humane system of non-restraint" could scarcely, by any possibility, have originated at Hanwell; but, once found practicable at Lincoln, it was successfully carried out at the more extensive establishment at Hanwell. And here, let

no remark, is a most powerful argument in favour of the opinion which I have held (ever since the second year of my house-surgeoncy at Lincoln), and which I am glad to find the commissioners recommending to the notice of the Lord Chancellor, viz., "That in any county asylum or hospital, hereafter to be erected, into which curable lunatics (either alone, or together with incurable patients) shall be received, the number of patients shall not exceed 250 in the whole." But to return to the assertion of the commissioners. Without positively contradicting their statement, I must confess that I saw nothing to bear out their assertion. One or two of the female patients were rather talkative, and perhaps the conversation of one might not be altogether suitable "for ears polite"; but can this be remedied in any hospital for the insane? A tyro might exclaim, "Oh, put the patient into seclusion!" Would that remedy the evil? Insane persons, like children, are possessed of considerable mobility; they must get rid of their accumulated excitability in some way and possibly the tongue in females may act the part of a safety-valve. I saw not a single indecent act; the patients appeared lively and contented, and their physical condition appeared to be good. I was much struck with the improved appearance of what was formerly the refractory gallery for the males: the window-guards had been removed, and I understood from the house-surgeon without any inconvenience having resulted. The only occupants of the day-room attached to the gallery were nine or ten patients, whom I understood to be epileptic, and, therefore, requiring extra supervision. The only thing I noticed at all bearing upon the subject complained of by the commissioners was this ("part of the airing-ground appropriated to the male patients runs under the windows of wards appropriated to females"), that the part herein named, which was formerly flagged to allow of the patients walking there, had been dug up, and stakes set down, which would deter the patients from approaching the windows of the females' apartments; so that the objection formerly raised by the commissioners has been removed. In this one case only the commissioners appeared to have been supported by facts. That persons not practically acquainted with the habits of the insane should advocate harsh measures or seclusive classification, in order (as they suppose) to overcome the noisy vociferation and restless habits of the insane, I am not at all surprised at. Two cases are forcibly recalled to my mind; both of them occurred at Lincoln during my house-surgeoncy. The first happened thus:—Whilst accompanying three or four of the governors through the females' refractory gallery, on the morning of a general-board meeting, one of the patients made use of threats and abusive language; a governor present, not very conversant with such matters (but certainly by no means possessed of a harsh disposition), recommended something very like the employment of the gag, but was taken up rather sharply by another governor present. The second instance occurred to me whilst accompanying a church dignitary through the wards in his capacity of weekly visitor. A female patient became noisy and abusive, when this gentleman, who was of a timid nervous disposition, recommended her being placed in seclusion; to this proposition I respectfully signified my repugnance, giving as a reason my belief that the patient, on being left to herself, would speedily recover her composure. The weekly visitor thought it his duty, however, to report the case specially to the board; and the matter was fully investigated at the next meeting of the governors, who decided in favour of the view which I had taken of the case. I mention these incidents, not from any feeling of hostility towards the gentlemen concerned, but simply to show how easy it is for persons of the most humane disposition to advocate measures replete with mischief and cruelty to the insane, simply from a want of proper knowledge of their habits and peculiarities; and amongst this mass of persons (I regret to state) the commissioners, or

some part of them, must certainly have a place.

The commissioners further report:—"This dietary does not seem objectionable, except that water is given instead of malt liquor; which is prohibited as an article of diet; contrary, we understand, to the opinions of Dr. Cookson (who preceded Dr. Nicholson as one of the physicians of the hospital), of Dr. Nicholson himself, of Mr. Graham (the late house surgeon), and contrary also, to the practice of almost every public institution for the cure of lunatics in England." Now, *prima facie*, it would seem that the commissioners had a strong case against the governors; but this is not so in reality. There is "much ado about nothing." I will venture to repeat the assertion of my belief conveyed in a letter addressed to a general board of governors, January 11, 1843:—"That the substantial nutritious dietary of the Lincoln Asylum is not surpassed in any other public asylum in this kingdom;" and, with reference to water being given instead of malt liquor, I would further remark, that a more extended experience (not only in private practice, but after a careful observation of the treatment pursued in our large and best-regulated asylums, visited since the writing of that letter) has only strengthened my faith in the soundness of the principles therein advocated; and so long as I find the physical condition of the patients at Lincoln to be in such a satisfactory state as appeared on my visit the other day—so long as I find them gaining flesh during every month of their stay there, and on their discharge (as I have witnessed in many cases) weighing considerably more than on their admission—I would earnestly but respectfully deprecate any attempt at returning to the system of stimulants, and the withdrawal of the increased allowance of animal food, so happily substituted in that establishment.

The commissioners next remark—"And here we think it right to call the attention of the board to the mode in which the medical department of this hospital is conducted. It will be observed that there is a president house-surgeon, or medical superintendent, who is prohibited, except in cases of extreme urgency, from prescribing for the patients; and also that there are three physicians, to whose skill and care the patients are intrusted, and who visit the hospital by rotation. It happens, unfortunately, that great differences of opinion exist between these three physicians as to the medical and moral treatment to which the patients should be subjected. One of them, Dr. Nicholson, advising classification, prescribing opiates occasionally to allay the restlessness of patients who are sleepless or in an excited state, and recommending the adoption of beer or wine as part of the ordinary diet, and frequently ordering them for particular patients; the other two (Dr. Charlesworth and Dr. Elmhurst) being adverse to classification, rejecting opiates in all cases, and ordering beer and wine very rarely, and then only as medicines in extreme cases, where stimulants or tonics are imperatively required.

"As each of these three gentlemen visits the hospital for a month only at a time, and during that period prescribes for the patients according to his own peculiar views, and apparently without reference to the plan pursued by his predecessor, the consequence is, that the patients in this hospital can never have the benefit of any uniform system or mode of treatment. Where a physician (Dr. Nicholson, for instance) has adopted a certain mode of treatment during his month of visitation, upon his retirement his system is immediately discontinued by his successor; he is not permitted, as in common hospital practice, to continue his mode of treatment until the patient is relieved or recovers, but his authority is immediately superseded by a practitioner whose opinions are known to be entirely opposed to his own.

"It appears, by 'The Physicians' Journal,' that Dr. Nicholson visited the hospital throughout the whole of August last, and that he was succeeded by Dr. Charlesworth on the 1st of September. It appears also (amongst other

things), that Dr. Nicholson, on the 30th of August, directed porter to be given daily to sixteen patients, and wine to one (named R.). On the 1st of September (the first day of Dr. Charlesworth coming into office) he ordered twelve of these patients to discontinue the porter, and R. to discontinue the wine. Now, this order of Dr. Charlesworth must necessarily have been given with a very imperfect knowledge, if any, as to the amount of benefit which the patients had received from Dr. Nicholson's order. Mr. Walsh, the house-surgeon, did not, as he stated, in answer to our inquiries, report against the wine and porter ordered by Dr. Nicholson; and it was impossible that Dr. Charlesworth could judge accurately as to the effects of those tonics (are they such?) or stimulants, inasmuch as he was not in attendance at the asylum, and could not, therefore, know the previous condition of the seventeen patients to whom the porter and wine had been given."

Now, what say the defendants, the governors, to these weighty and serious charges? And here allow me to compliment them upon the critical acumen and profound sagacity which has urged them to retain as counsel the high intellectual acquirements and great moral worth of a retired barrister and two very pious divines! Some persons, in their unsophisticated ignorance, might have deemed this a proper subject for the medical staff, which boasts of three physicians, three surgeons, and a fully-qualified resident surgeon! But no; the Lincoln governors are a *race sui generis*; ay, marry, they are a far-sighted generation!

In reply, the governors passed resolutions four and five:—

"That the regular attendance of the physicians of the establishment is one of its most peculiarly commendable features; and that, so long as it continues, no advantage can possibly accrue from adding to the power or altering the duties of the house-surgeon.

"That the custom of three physicians attending the asylum in monthly rotation, as has been practised since the opening of the institution, secures to every chronic case the advantage of multiplied medical opinions, and does not require alteration."

Now, were I requested to point out the principal defect in the Lincoln establishment, I should at once refer to the anomaly of having three physicians, three surgeons, and a fully-qualified resident-surgeon to an establishment containing 117 patients (*vide* "Weekly Return," Dec. 29, 1843), whilst the immense asylum at Hanwell, containing 1000 patients, has but one visiting physician and two resident surgeons. I need not refer to Hanwell alone; what obtains at Lancaster, Northampton, Gloucester, Chester, Nottingham, and many other large and well-conducted establishments? The management of Lincoln, in this respect, is certainly unique; hence, probably, arose the sobriquet of the "Non-paral Establishment," by which it is known amongst the superintendents of similar institutions.

If we may "judge of the tree by its fruit," what must we think of the bickerings and angry discussions which have agitated its medical staff for a period of nearly twenty years, almost without any interval of repose? Have not its medical officers been continually at variance from the days of Mr. Thomas Fisher, the first director, through those of Dr. Cookson, *primus et secundus*? And further, the apple of discord appears nowise diminished in the hands of Dr. Nicholson, one of the present physicians! What shall we say of a public medical charity which, in the short space of sixteen years, has had no less than six resident medical officers, viz.: Messrs. Henry Marston, Samuel Hadwen, Robert Gardiner Hill, Wm. Smith, Wm. Graham, and Mr. Walsh, the present house-surgeon? The attendants too (or, as the learned commissioners would style them, the keepers and nurses) have fared very little better. Of twelve attendants whom I left behind me in June, 1844, three only are now remaining! viz., the head male attendant, the

house-porter (who also acts as an attendant), and one female attendant; and, what still further demonstrates the absurdity and mischievous tendency of the Lincoln rules, this very house-porter (who, by the way, is a most valuable servant) had a narrow escape of dismissal in consequence of having committed the unpardonable error of getting married. So much for their Malthusian doctrine! Dr. Corsellis, the experienced and much-esteemed director of the Wakefield Asylum, gives a severe but I fear too truthful sketch of Lincoln management—*Lancet* 1839-40, vol. 2, page 247:—"I know so well the difficulties which encompass the path of the superintendent of a lunatic asylum, the liability of his best exertions to misrepresentation, his exposure to attacks emanating only from feelings of personal malignity, and motives of which every honest man would be ashamed; the petty cavillings and opposition he is often called to undergo, from those who wrap themselves up in fancied notions of their own excessive wisdom, and practically know nothing; whilst censure, the lowest exercise of the understanding, is considered as fairly employed on him, by would-be authors, devoid of talents capable of any higher range; and, feeling this, it is with delicacy I allude to the Lincoln Asylum. Without particularizing my motives, I would merely remark, that the very frequent change of officers and servants in that institution does not speak much for the working of the system. I would say of a public institution as of a private family, where such changes are unusually frequent, your fault is less in your men than your system. Look to it that your main-spring be not wrong; you are perpetually introducing novices, by which the interest is broken and confidence destroyed; and no sooner do they become initiated in the discharge of duties the most difficult to which man or woman in any station of life can be called, than the benefit of their experience is lost to the patients, and other novices take their place. The superintendent of a lunatic asylum requires to have his zeal tempered by extraordinary prudence, his exertions supported by extraordinary coolness and patience, otherwise he will only increase his difficulties until they are altogether insurmountable." Now, be it observed, these remarks are not from the pen of a raw youth or an idle theorist; they are the deliberately recorded sentiments of a gentleman who has passed nearly twenty years of his life in the active duties of medical director to a large public asylum,—Wakefield contains more than 430 patients,—a gentleman who is esteemed by his contemporaries, not only for his zeal and humanity in the cause of the insane, but likewise for the courtesy and general urbanity of manners which he displays towards those who may entertain views somewhat opposed to his own. The Seventeenth Report of the Lincoln Asylum, page 29, contains in a foot-note the following remarks:—"Without efficient officers, honestly and zealously willing to co-operate with the authorities, no superintendence, no rules, can be of any permanent use. An unwilling officer can thwart the best-arranged plans, without subjecting himself to any specific charge: he can contrive that an improved system shall not answer, or can arrange that any convenient plan of his own shall become necessary, or can affect to misunderstand; or can distress officers who are honest in their duty, or can countenance a faction of an opposite character, or can raise difficulties, and may always avoid offering expedients." Now, if the Lincoln physicians be arrayed two against one, if the house-surgeon be fresh to his duties, if he keep having a constant succession of attendants unacquainted with the management of the insane, what, let me ask, can be the state of the establishment? Dr. Conolly, the talented physician of the Hanwell Asylum, has so admirably described what the management of an asylum ought to be, that I cannot resist giving an extract from his seventh lecture (*Lancet*, Oct. 3, 1846). "On the Construction and Government of Lunatic Asylums":—

"An asylum ought to be neither a prison nor a workhouse; but a place of refuge and recovery from all the mental distractions incidental to mankind. Comfort in all cases, and recovery in many, are the attainable results of proper agencies directed to the remains of affection and intelligence, existing in every case, and varying in all cases. The object, therefore, of every care and regulation of an asylum, of its whole constitution, should be to bring to bear on all the patients such an amount of intelligence and benevolence as may soothe many and direct all, and raise each patient to the point of cure attainable in each particular case. All the details should be part of one harmonious whole. The patients should be accustomed to look on the attendants as their constant friends and guardians; the attendants should expect the visit of the officers with pleasure, and rely upon them for advice and encouragement; the officers should be animated by the example of a humane and intelligent medical superintendent, and he and they should look forward to the occasional visits of the directors with confidence. If the patients fear the attendants, and the attendants dread the officers, and the officers look forward to committee days as days of insult, all must go wrong.

"The medical superintendent himself should deserve the fullest confidence of the governing body, and should possess it. His representations should always be received with respectful attention, and his complaints of neglect of duty, or of departure from his plan of managing the asylum, should be investigated promptly, openly, and with care. His authority cannot be impaired without detriment to the asylum, through every part of which his influence must be continually in operation. Whatever diminishes his influence, and whatever discomposes his mind, disqualifies him for the task of superintending the whole working of the asylum, and for consoling, enlivening, animating, and, by undisturbed kindness and calmness, ever guiding, supporting, and controlling, more or less directly, the minds of all the rest of the establishment. It is to him that the whole house must at all times look for the principles by which everything done in it is to be regulated. His supposed or his known wishes should be present to the mind of every officer and every attendant in every variety of accident, and his character of mind and heart ever in their view. Indifference on his part must lead to negligence on the part of those who execute his commands; severity exhibited by him must lead to brutality on the part of the attendants. His steady discouragement of negligence, his known abhorrence of cruelty, and his real and deep sympathy with his patients, may be reflected from every humane heart in the asylum.

"His duty is difficult and peculiar, and comprehends a wide and careful survey of everything that can favourably or unfavourably affect the health of the mind or the body. He has to regulate the habits, the character, the very life, of his patients. He must be their physician, their director, and their friend. The whole house, every great and every trifling arrangement, the disposition of every officer and servant, should be in perpetual conformity to his views, so that one uniform idea may animate all to whom his orders are intrusted, and the result be one uniform plan. Nothing should be done without his sanction. The manners and the language of all who are employed in the asylum should but reflect his; for everything done and everything said in an asylum is remedial or hurtful; and not an order should be given, or a word spoken, except in accordance with the spirit of the of the director of the whole establishment. By such a system alone can it ever be proved to what extent the cure or improvement of the insane is practicable."

Now, if this be a faithful picture of what the management of an asylum should be—and undoubtedly it is so, since it was sketched by a master-hand, and emanated from the mind of one who has, for more than seven years, ably presided over the largest establishment for the in-

sane in this kingdom—if these views be correct, what must we think of Lincoln management, where the three physicians are at open warfare, and scarcely agreed upon any one point of treatment, medical or moral; where the house-surgeon has the semblance of power without the reality; where attendants are constantly going and coming; and where the governing body itself is divided as to the merits of its rival physicians? Would any man, possessed of one iota of common feeling or common sense, send an afflicted relative to an establishment where such unnatural divisions exist? Let the governors look to it; they have lost the confidence of the public, and the management of the Lincoln Asylum has become an object of ridicule amongst the superintendents of similar institutions. The credit of a public medical charity cannot be supported by self-laudatory reports written and passed by a certain clique, *ad captandum vulgus*; the public expects to find unanimity prevailing amongst the governing body; the whole establishment placed under the management of an able and experienced (not under the auspices of a succession of raw youths just emerging from their *alma mater*) medical superintendent who is worthy of, and possesses the entire confidence of, the governing body and supplied with a set of well-informed and steady attendants; and last, though not least, that every individual of the governing body, shall refrain from interfering with the orders and directions of the resident officers, who have, or ought to have, the entire control of the establishment in the intervals between the meetings of the board.

As it appears highly probable that Dr. Nicholson, one of the present physicians, will be sacrificed for the part which he has taken in the late encounter with the commissioners in lunacy, I would earnestly recommend the governing powers to pause ere they elect a fresh physician, for by so doing they will assuredly keep alive the flame which has burnt so fiercely (with one or two short intermissions) for upwards of sixteen years.

Were I offered the post of honorary physician to the Lincoln Asylum to-morrow deeply as I feel interested in the treatment of insanity, on condition of carrying out the present system, and turning over all my patients to a fresh physician at the end of the month, I would respectfully decline the honour, feeling thoroughly convinced after seven years' practical acquaintance with insanity, three of them spent in the active duties of house-surgeon to the Lincoln Asylum, that the system as at present pursued at Lincoln is prejudicial to the welfare and cure of the patients, unfair alike to the medical officers and those under their authority, and in one word entirely opposed to common sense; and such undoubtedly (could it be ascertained) is the candid opinion of three-fourths of the medical superintendents of our largest and best-conducted hospitals for the insane.

King-street, Belper, Tuesday, April 6.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF MEDICINE.

Meeting of March 30; M. BEGIN in the Chair.

INHALATIONS OF ETHER.

The debate continued on this subject;—M. Blandin insisted upon the dangers of the inhalation, particularly when complete insensibility was produced; he contended that a method which caused a conversion of arterial into venous blood could by no means be looked upon as innocent, and was of opinion that it should never be employed in operations performed on the mouth, on account of the additional danger of complete asphyxia, from the passage of blood into the trachea and bronchi.

M. Velpeau and M. Roux could not agree

with M. Blandin in his fears; they considered the dangers alluded to as in a great measure theoretical; and M. Roux stated that complete insensibility was far preferable to the condition produced in the second period of the effects of ether, during which irritability had on various occasions been evidently increased.

M. Denonvilliers presented a cerebriiform tumour, removed from the leg of a woman of seventy. Ether had been employed, and complete insensibility obtained during three quarters of an hour. The first two days which followed the operation were marked by stupor and quickness of the pulse, but the circulation had since then descended to its natural standard, and the patient was now doing well.

EXTRACTS FROM MEDICAL PERIODICALS.

DIAGNOSIS OF CEREBRAL HEMORRHAGE FROM RAMOLLISSEMENT OF THE BRAIN.—The sudden occurrence of paralysis from apoplexy, its gradual appearance in ramollissement, are the circumstances upon which the diagnosis is generally founded. Admitting the value of this sign, M. Chomel does not consider it sufficient in all cases to establish positively the diagnosis. The learned professor is of opinion that temporary return of activity in the cerebral functions after the seizure, or preservation of the intellect coinciding with complete and intense hemiplegia, indicate ramollissement, and not hemorrhage. — *Journal des Connaissances Médico-Chirurgicales.*

TREATMENT OF ARTICULAR RHEUMATISM WITH SULPHATE OF QUININE.—This method was first introduced into practice by the Italian school, who considered the drug as a powerful contra-stimulant, exercising a depressing influence on general irritability, and acting specially upon the heart and arterial system. In France, M. Briquet, M. Guérard, and Professor Fouquier have employed sulphate of quinine for the treatment of acute articular rheumatism, with the most satisfactory results, the dose varying from 3j. to 5j. daily. — *Ibid.*

Sulphate of quinine can be deprived of its bitterness by being taken in coffee: M. des Vovues, who recommends the method, has found the medicine equally efficient in this form, and asserts that its bitter taste completely disappears. — *Revue Médico-Chirurg.*

TREATMENT OF BURNS.—M. Guérard recommends in burns the application of caustic hart-horn; the application of cloths steeped in ammonia immediately relieves the pain. Ad must be continued for one hour after the accident. When the burn has produced any destruction of the skin, ammonia should not be used; but in the erythematous form, or when phlyctenae are present, it is of the greatest advantage. — *Annales de Thérapeutique.*

FACULTY OF MEDICINE.

LECTURES ON GENERAL PATHOLOGY, BY
PROFESSOR ANDRÉA'

The word crisis (so often used means separation or judgment. Hippocrates gives various meanings to the word: in one book he tells us that a crisis is constituted by increase, diminution, transformation, or cessation of a malady; in another book a crisis is stated to be any change whatever occurring in disease; elsewhere it is the solution of disease. Galen admitted the existence of a good, a bad, and an imperfect crisis. The first was constituted by a sudden return to health immediately after or simultaneously with a certain disturbance. The crisis was bad when the perturbation was followed by death; incomplete, when partial relief only was obtained.

The doctrine of the ancients on this subject involves an entire theory on the expulsion of the morbid principle through the various excretories. The appearance of phenomena of four orders marked the crisis:—1st, hemorrhages; 2nd, discharge of certain matters, such as abundant perspiration, or of urine, of considerable sediment in that fluid, diarrhoea, expectoration, pyelism, &c.; 3rd, excretion of morbid products, such as pus, formation of abscesses, &c.; 4th, exanthemata.

Some phenomena were said to usher in all sorts of crises indiscriminately, e. g., general uneasiness, sleeplessness, delirium, chills, flushings, pain, or a temporary exacerbation of disease. Other symptoms were considered as announcing more particularly the approach of each particular variety of crisis, such as congestive appearances, heat, hemorrhage, itching of the skin previously to perspiration, and an undulating pulse, which was also looked upon as premonitory of the same issue. A crisis furnished by the urine no precursory signs; Galen believed this sort of crisis did not cause any disturbance in the system. Flatulency, and lumbago, gave warning of an intestinal crisis.

Each malady was proved to have a special form of crisis peculiar to itself: in essential fever without any local action, the urines were critical; in inflammatory fever, that secretion contained a white deposit; in bilious fever, a red sediment. Cerebral lesions were judged by three forms of crises—pistaxis, parotidian swelling, or perspiration horacae affecting, by the sputa. Affections of the convex surface of the liver presented a singular sort of crisis, viz., hemorrhage from the right nostril. Diseases of the concave aspect of the liver were judged by bilious stools. Age, sex, temperament, seasons, reigning epidemics were as many circumstances which caused these various crises to vary in their form. Thus, for instance, the same disease which might be judged by mild pistaxis in a child, would in the adult be terminated by hemorrhage, or in man by uterine flux.

But this was not all: certain days were admitted to be more favourable than others to the appearance of critical symptoms, and in this respect the theories of ancient writers present a considerable degree of complication. The seventh, fourteenth, and twentieth days were of all the most fortunate; the ninth, eleventh, and sixteenth were less so; a happy issue was still less to be expected on the third, fourth, or fifth days; the sixth was decidedly a bad day.

It was also believed that some days presented symptoms indicating the coming crisis: thus on the fourth day it was said that the crisis of the seventh and its nature might be foretold; the seventh day indicated the crisis of the fourteenth, the seventeenth, or the twentieth. Medicines were exhibited only on those days which were neither critical nor indicative of crisis; they were medicinal days.

After this rapid glance at the doctrines of the ancients on this subject, let us now examine if they must be rejected *in toto*, or if they contain some truth in the midst of many errors.

Some diseases, eruptive fevers for instance, present fixed periods, a determined length, and during their course it is possible to assign peculiar phenomena to certain days; but it is not so in all diseases: observation does not authorize us to say that on a given day a malady will assume a peculiar form, or present a favourable or unfavourable termination. The ancients, not being always able to point out the exact day on which the disorder began, could not number the days with any satisfactory degree of precision, and were much divided amongst themselves on the subject of the crisis of the twentieth or twenty-first day. The Hippocratic doctrine of critical days is therefore not admissible. Celsus, who does not believe in it, says that his predecessors had been led astray by the dogmas of the followers of Pythagoras; and we find in reality that Hippocrates was much attached to the science of numbers, which could, in his opinion, indicate the progress, crisis, and transformations of disease. Galen has not a very strong faith in the doctrines of crisis: in one passage he goes so far as to say that he admits them, on the pressing solicitations of his friends.

We must not, however, refuse to believe in the existence of critical phenomena, i. e., of occurrences coinciding with an improvement in the symptoms of disease: for instance, hemorrhage frequently relieves plethora or local congestions; critical perspirations have been observed to terminate various maladies, and amongst others,

serous effusions. Mucous fluxes also occasionally coincide with improvement of some disorders: thus Pinel and Esquirol state that in mania much advantage is often derived from the presence of diarrhoea; hence, the indication of purgatives. Bilious or urinary fluxes may also be observed, but they should not be admitted as critical, without much severity of observation; for instance, urine was for the ancients the chief vehicle of critical appearances; when, during the progress of acute disease, the urine became turbid and sedimentous, they concluded that the intensity of the malady had yielded. Observations teaches us that precisely the contrary is the truth; it is a fact which cannot admit of doubt, that the urine, turbid and sedimentous when febrile excitement is at its height, and returns to its natural transparency when fever is diminished. Chemical causes also, of which the ancients had no idea, exercise on the appearances of the urinary secretion an all-powerful influence. Cutaneous eruptions sometimes succeed in arresting concomitant disease. We may, perhaps, give also the name of critical to those violent nervous disturbances which occasionally interfere with the progress of existing maladies.

From these remarks we conclude that crisis is a possible but by no means a necessary phenomenon of acute or chronic disease; that in eruptive fevers the doctrine of crisis adopted by the ancients is fully borne out; unfortunately they were not acquainted with smallpox, which illustrates so perfectly Sydenham's definition—"Morbus, nature comenae materiae morbosae exterminationem, in regis salutem, omni ope molientis."

We have said that disease may terminate by death, or by a return to health; it may also pass, if chronic, to an acute state, if acute to a chronic form; and, lastly, by conversion into another malady.

This last termination is practically most important, and is frequently observed in phlegmasia; thus, after acute inflammation, the cause of phlogosis having ceased, the vessels still remain dilated, an accumulation of blood continues to take place in the affected part, and passive hyperemia is established, together with new practical indications; an increased secretion—a flux—may also remain, as the trace of inflammation—a mucous membrane; dropsy occasionally follows departed inflammation of serous textures. Oedema, or accidental products, may also be observed after phlegmasia of parenchymata: an alteration of function, neurosis, may be likewise observed after acute inflammation.

This transformation is not particular to phlegmasia; neurosis may also change its nature; congestion or inflammation may succeed neurosis. A nasal or lachrymal flux is not uncommon after facial neuralgia. After continued disturbance of the function of an organ by neurosis its texture may become altered—a fact, perhaps, less rare than it is generally supposed: for instance, hypertrophy of the heart certainly sometimes results from nervous palpitations. Pulmonary emphysema has occasionally its origin in a succession of purely nervous attacks of orthopnea, &c.

Without being changed in nature, a disease may occupy a different seat; this is metastasis, and is frequent in congestions and inflammations. This metastasis or delitescence is common in erysipelas, in gout, in the family of herpetic diseases; the skin and mucous membranes seem to have a great tendency to be alternately affected—an analogy in disease explained to a certain extent by the analogy of their relative functions.

The intermediate state between health and disease is called convalescence: it begins with the disappearance of the symptoms of disease, and ceases when the various functions are restored to their freedom and regularity. We will study its various phenomena in the different functions, and with their description close our course for this session.

Digestion.—In some cases appetite returns as soon as disease is terminated, and the stomach appears to be unusually active; in others the

appetite is more easily satisfied; and in a third set, dyspepsia is present; and, although the desire for food is strong, the gastric organs cannot elaborate the nutriment. Occasionally the appetite does not return: in these cases bitter draughts, associated with gentle purgatives, are of the greatest benefit. Diarrhoea, during convalescence, is far from rare; prolonged abstinence may be the cause of some suffering; in general, when the stomach has not been the seat of disease, prolonged diet has weakened the stomach and that viscous requires a stimulus.

Circulation.—On the slightest exertion, palpitations of the heart are frequently observed; with regard to the pulse, it usually returns to its natural standard; but it may remain frequent during digestion, or after indigestion, or mental excitement. This is frequent in children and women. But when the pulse remains quick during repose, and does not diminish by the daily exhibition of food, some anxiety is warranted. Anemic murmurs are heard in the heart and carotids when debility has been considerable; it is a singular fact, that often these vascular bruits appear for the first time some days after the establishment of convalescence; the circumstance is due to the diminution of the blood discs, which continues to take place for a certain period beyond the duration of the original complaint. The capillaries, during convalescence, generally remain pale; in repose it is not a favourable sign to see them assume a red colour, which would indicate the persistency of febrile excitement. The paleness of convalescents lasts sometimes very long.

Temperature.—During recovery from disease, loss of heat is repaired with considerable difficulty, hence convalescents, like children, should be carefully protected from cold. It is for the same reason that convalescents are chiefly exposed to those maladies which result from the influence of cold, viz., pneumonia and rheumatism.

Respiration may be more or less difficult, as in chlorotic patients, particularly after slight exercise. The voice is generally extremely weak, and may remain so for ever.

Secretions.—Serous infiltration, merely attendant upon debility, is less common than it is supposed. When oedema acquires by its extent any degree of importance, it is almost always connected with particular affections already noticed in these lectures. The secretion of fat is often extremely active during convalescence; indeed, it is not unusual to see patients become after a severe fit of illness stouter than they had ever previously been. The perspiration is frequently abundant, and gradually diminishes in proportion as strength is acquired. The hair may fall, or be modified in its colour; desquamation of the epidermis is sometimes observed. The urine is remarkable by its abundance and pallor. When that fluid is turbid or sedimentous, some internal cause of suffering should be sought for, and, if possible, removed.

Cerebral Functions.—The intellect is at first weak, and may even for a time be, to a certain extent, perverted. Changes of temper are common, and a special mania of convalescents has been described: the sensibility of the patients is usually much excited, and the neurosthenic state established. Muscular contraction is weaker than in health, and is often attended with pain; cramps are also very often observed. The menstrual function is often suspended for some months after severe illness. Convalescence lasts a very variable time. In this respect it is influenced by many causes; amongst which we may notice ages, constitutions, the nature of diseases or of the treatment resorted to, and the seasons.

D. MCCARTHY, D.M.P.

SURGICAL SOCIETY OF IRELAND.

Saturday Evening, Feb. 20.—J. KERIN, Esq., in the Chair.

INJURY OF THE SHOULDER-JOINT.

The following case, transmitted by a physician

of Portarlington, in a letter to Professor Hargrave, was laid before the society.

A short time since B., a slight, spare girl, aged sixteen, applied to the physician for relief under the following circumstances:—She stated that between two and three weeks before, while crossing the kitchen, she stumbled and fell, the upper part of her left arm coming across the edge of a large iron pot, which happened to be in the way. Though feeling much hurt at the time, she endeavoured to bear till now, when, not finding the use of the arm returning as rapidly as she expected, she applied for advice. On examination, some of the unequivocal signs of dislocation into the axilla presented themselves, viz., a hollow beneath the acromion and the head of the bone, distinct felt in the axilla; but the arm was not greatly lengthened, nor was the elbow thrown out on the side; rotation of the bone at the elbow also rotated in a slight degree the head of the humerus. Regarding the case as one of common dislocation, the necessary proceedings for reduction were adopted, and in about two minutes, after gradual and steady extension had been made, the physician was sensible of its effect and then a sudden giving way; the bone, however, was not reduced, on the contrary, he had perceived a fracture of the neck—to very pleasing effect at the moment. He considered, however, that there was now nothing to do but to replace the head into the glenoid cavity, as by the back of the shaft all antagonizing power of the muscles was removed, and then treat the fracture; but in this he was totally failed, not being able to accomplish it by any means. On further inquiry, it was ascertained that, two years before, the girl had met with some injury of the joint, from a fall over a ditch, and for which she never sought advice, but from that to the present period she never could raise her arm horizontally, keep it close to her side, the only use she had of it being backwards and forwards and under her. The true nature of the case was now evident, namely, the dislocation had existed two years, an adventitious socket having, of course, formed on the inferior costa of the scapula; the recent injury—fracture of the neck—was caused by the fall across the edge of the pot, and was in progress of reunion when it came under observation, and was broken up in the effort to reduce the dislocation. The case was then treated as one of simple fracture of the neck of the humerus, and in due time got well without any untoward event, the girl stating that she had as perfect use of the limb as ever she had since the first accident, but, of course, not as extensive as of the right, the dislocation still existing, as it was not deemed practicable or prudent again to attempt its reduction.

There was one defect remedied, namely, enabling her to place her arm closer to her side, by allowing the union to take place at a slight angle, and which she says is a great matter to her, as she never could lie comfortably on that side. This, perhaps, could not have been prevented, and certainly no attempt was made to do so.

DISSECTION OF THE EAR, LIGAMENTUM NUCHÆ, &c., OF THE ELEPHANT.

Professor Harrison next directed the attention of the society to the anatomy of certain parts of the elephant: he first exhibited the "ligamentum nuchæ" to which he had alluded at the last meeting as being so essential in sustaining the head of this animal, which, on account of the tusks and proboscis, is of considerable weight. This ligament is a mass of elastic yellow tissue adhering to the spinous processes of the upper dorsal and lower cervical vertebra; as it passes forwards to the head it divides into two deep vertical plates separated by cellular tissue and bloodvessels, and these are inserted into the fosse of the occipital bone on each side of the prominent crest. While this structure possesses prodigious strength, it is also eminently elastic, as might be seen by separating a small portion and extending it. It consists of numerous fasciculi parallel to each other, and, although

these are partially distinct, yet each fasciculus gives off processes to join each adjacent fasciculus, whereby the whole structure co-operates in sustaining the weight and obviating any great strain on any one portion. The mode of attachment to the occipital bone is peculiar and worthy of observation; within three or four inches of this, each yellow fasciculus ends in a small round silvery tendon, in the same manner as the fleshy fibres of a muscle join the tendon of insertion. Each of these tendons is deeply inserted into a rough depression in the bone, the design of this arrangement being to condense or concentrate into a small space the attachment of this large mass, and to secure a more intimate adhesion to the bone than the elastic tissue could effect. Although each tendinous cord is continuous with each elastic fasciculus, yet the tissues are perfectly distinct; immersion in acetic acid causes the most decided difference, the tendon being converted into a transparent hyaline pulp, while the yellow tissue is but little affected, being merely opened out or unravelled into its elementary elastic fibres.

Mr. Harrison next presented a dissection of the ear of the elephant; the meatus externus, the membrana tympani, the ossicula auditus, the stapedius and tensor tympani muscles, the chorda tympani nerve, the Eustachian tube, &c.

The external bony meatus is remarkable for its great size and length—between six and seven inches, leading inwards and a little downwards with but a little obliquity, and surrounded by the cells which separate the two tables of the skull. At its inner extremity is the membrana tympani, larger than a shilling, and placed very obliquely, being rather on a line with the posterior wall of the meatus than directly opposite to this tube. By holding the preparation before the candle the membrane was very distinctly seen, the tympanum being opened on the inner side and a portion of the bony meatus having been removed. This beautiful septum presented a deep concavity towards the meatus, and a convexity towards the tympanum, the strong manubrium of the malleus setting it firmly in that form. When examined against the light the radiating fibres are very distinctly seen, converging from the outer border towards the centre of the membrane and the handle of the malleus. These fibres have been considered muscular by Sir J. Home, who has given a minute description of them in "The Philosophical Transactions" for the year 1823, and in his "Lectures on Comparative Anatomy," vol. iv., page 98; it is by no means clear, however, that these fibres are muscular; in the first place, the existence of such a structure in a vibrating membrane does not appear to be requisite; and in the next place, if the fibres be carefully pursued, they can be traced into the periosteum lining the external meatus, where they present the same radiated and glistening appearance, and appear to be also a continuation of that tissue. Mr. Harrison, therefore, expressed a strong doubt as to the muscularity of this structure, and felt disposed to regard it as white fibrous tissue; his reluctance, however, to injure the preparation had precluded him from testing any of the fibres in the microscope, which, however, he was determined to do in some little time. As a great similarity exists between many parts of the elephant and of the human subject, so there is a striking correspondence in the membrana tympani; in each it is very concave externally, and this concavity cannot be effaced by pressure from within. This led Mr. Harrison to notice the opinions of some writers who consider that this membrane is convex towards the meatus externus during life. Mr. Harrison conceived that the strong illumination caused by the rays of light passing down the speculum auris, together with the projection of the upper part of the manubrium of the malleus, gave to the eye of the observer the appearance of a full or convex surface, and he proceeded to show by a simple experiment that the concavity so constantly found in the dead body depends not upon any post-mortem change, but on a fixed and determined form owing to the attachment of the malleus. The experiment was this: the recent cranium of

a child was placed before the meeting, with the external ear and meatus on each side removed, and the two membranes exposed without any violence or injury. A blowpipe was then introduced into the Eustachian tube, first on one, and then on the other side; a slight inflation immediately moved the membrane, elevating and rendering its circumference a little full and convex, but not producing any effect on the central depression. By alternately increasing or lessening the distending force, the movements of the membrane were quite distinct, but no degree of force could raise the central depression; on the contrary, it appeared increased in depth as the circumferential portion of the membrane became distended, and it was obvious that the structure would burst before the central convexity could be effaced.

Mr. Harrison then pointed out the position of the three auricular bones (there being no appearance of the fourth, or orbicular); he remarked that there was one very important difference in the relative position of these parts in this animal as contrasted with man. In the latter, the membrane of the fenestra vestibuli is opposite to the membrana tympani, and the chain of ossicula, which connects these bones like a curved spring or a bellcrank, traverses the cavity of the tympanum. But in the elephant, the vestibule is above and rather behind the tympanum, and on a level with its outer wall; the bones therefore do not cross the chamber, but are placed obliquely behind it, and the long crus of the incus is bent outwards, and the stapes has the same aspect. The stapedius muscle was next exhibited, and was a distinct fleshy mass exposed by opening the pyramid; its silvery tendon was seen inserted into the neck of the stapes; any doubt entertained as to the true muscular nature of the stapedius could be therefore removed by inspecting it in this dissection. The tensor tympani holds a different position from what it does in man; it is placed external to the membrana tympani, in the bony meatus between the bone and the lining membrane, and is inserted as usual into the upper part of the malleus. The Eustachian tube is about eight inches long; the bony portion is wide as it opens into the tympanum; the calibre contracts very much as the osseous and fibro-cartilagenous portions join; it dilates again anteriorly, but its nasal aperture is smaller than its tympanic. Mr. Harrison also remarked that the external cartilaginous meatus is much smaller than the osseous tube; the cartilages of which it is composed admit, however, of considerable motion, and can be acted on by different muscles, so that the canal can be dilated or contracted.

Mr. Harrison next made some general and physiological remarks tending to explain some of the peculiarities seen in this dissection, as contrasted with the human ear, and concluded by stating that the highly developed condition of the acoustic organ in this animal tends to establish the fact noticed by many observers—namely, that the elephant possesses the sense of hearing in an eminent degree.

DEATH FROM STARVATION.

Dr. Leeson said that he had been called upon on the previous Monday to make a *post-mortem* examination, in conjunction with Dr. Brady, Professor of Medical Jurisprudence in the College of Physicians, on the bodies of two individuals, a man and woman, who had died suddenly, and, as was reported, from starvation. One of them died on Saturday evening, the other on Sunday morning. Upon external inspection both bodies presented appearances of extreme emaciation. All the features of the female were remarkably contracted, the eyes sunk, nose pinched, and cheeks drawn in, giving her the appearance of a person upwards of sixty years old. The rest of the body was proportionally emaciated; the spaces between the metacarpal bones were perfectly hollowed out; the abdominal parietes, when cut, were totally devoid of the fat always met with in other subjects, and all the abdominal contents were perfectly bloodless: every organ was completely anemic.

On cutting into the stomach, its rugae were observed to be remarkably developed, and there was not a trace of food in it. The whole track of the intestines, though cut into in several places, had not the slightest trace of fecal matter—containing only a little fetid mucus. There was some ulceration of the intestinal glands at the lower extremity of the ileum. When the chest was opened, both lungs were emphysematous and perfectly anemic. The left ventricle of the heart contained half an ounce of remarkably thin fluid blood.

The body of the male presented similar appearances, but the external emaciation was even much greater. The stomach contained a very small quantity of fluid, with a few grains of meal, but no trace of feculent matter was observed until near the termination of the intestine, and even here its amount did not exceed a teaspoonful. The lungs were in a similarly emphysematous and anemic condition, and the heart contained a small quantity of fluid blood. The gall-bladder, as usually observed in cases of death by starvation, was remarkably full, and the liver was lobulated, its eminences, however, being of a healthy kind.

In giving an opinion as to the cause of death here, Dr. Leeson remarked, that from hearing the facts of the case—that up to the last period of their existence these poor creatures had something to live on—it could hardly be distinctly stated that they died of starvation; nor, indeed, do we find death from absolute starvation to be by any means a common occurrence, taking as an example, for instance, death by starvation in consequence of several weeks total deprivation of food, as in cases of shipwrecked mariners, &c. In the present instance, however, it appeared that this poor man and woman, with six children, lived in the county of Leitrim, and, seeing the destruction of the potato crop, made their way up to town, where the whole family were huddled into a miserable apartment, not more than six feet square, with a damp floor and a roof that admitted the rain, a wall of straw, that might now have passed for any other material, being its only furniture. Reviewing all the facts of the case then—their destitution previous to coming to town—their bare subsistence while here, having only a sum of 1s. 3d. a day for the support of six children and themselves—life, in fact, as well remarked by Dr. Brady, gradually ebbing away—the opinion given was that death had arisen, not from actual starvation, but from the state of general destitution in which they had so long existed—in want of lodging, fire, clothing, or proper nourishment.

He might here observe that it is well known the soup obtained by such poor creatures as the above from the soup shops is entirely insufficient for the support of life, without some addition of solid material; and this is more particularly true in reference to Paoli's parish, where this man and woman lived, the soup there, from the poverty of the parish, being little more than meal and water, which, in the entire absence of solid food in the stomach, passes through the intestinal tract as it is taken in, or gives rise to diarrhea. The facts of these cases led him to suggest that a certain quantity of solid food might be allowed once or twice a week, to the suffering poor, in addition to the distribution of soup, and to hope that some notice of the subject might be taken by the public prints.

After finishing the *post-mortem* examination of the above cases, they proceeded to an adjoining apartment, the area of which was certainly not more than six feet square, and here lay (if he might use the expression) a mere living skeleton, stretched on a portion of straw, the eyes sunken, and their whites suffused, cheeks hollow, nose pinched—in fact, absolutely famishing, unable to move, and just able to call, in a voice that reminded him of the voice in cholera, for a little water, stating that her mouth was like the burning fire, and it was perfectly parched. The emaciation was so great that her arms were no thicker than candles, and the legs were swollen. She was unable to say when she had tasted food.

In reply to a question, Dr. Leeson stated that no urine was contained in the bladder in either case. Delirium, he believed, too, is only observed in cases of absolute starvation, not in those of gradual starvation as here.

TO CORRESPONDENTS.

THE MEDICAL TIMES may be procured by an order on any Newsman or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carfrae, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 12s.; Quarterly, 6s. 6d.

A HANDSOME PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 5s. An allowance is made to the trade.

Medicus, on the Birkenhead Hospital, is making a storm in a puddle. Surely so small an affair might be below personal acrimony, especially "in amnis celestibus."

Dr. John Thompson affirms that "Mr. Synne, under a clumsy mask, has induced us to make an improper use of Dr. Thompson's name," in our last number, and wishes us, to escape a "harsher mode of expunction," by reprinting a pamphlet of his, "On Cruelty in the Infirmary." The pamphlet is no answer to the letter published by us; and, secondly, if it were so, we are not the people to do favours "on compulsion."

Mr. Kendall informs us that Mr. Vidal, of Avely, is not leaving that neighbourhood, and that the testimonial to him was given out of esteem from long acquaintance.

A. L. D.—Mr. Henshaw is the publisher of Dr. Guy's "Medical Jurisprudence."

P. B.—The fact inquired about is rarely or never possible.

Inquirer.—The dresser is not justified in good sense, though he may be in morality, in assuming the title Inquirer speaks of.

A. M., who asks if chloride of lime might not have as good an effect in a diseased stomach as in a foul pit or well, cannot do better than renounce all his medical opinions for which he has not the sanction of some medical friends.

Dr. Hubbard's reply has been received.

Mr. Halle is thanked for his offer which is declined. His views are fully expressed in the extract sent, and which we shall content ourselves with printing—

"Nervous substance, we repeat, is but the recipient and vehicle of external and internal impressions. To every phase of emotion there is a coincident phase of mind or emotional conception, of which the former is the immediate consequent and expression; the instrument of expression, or the means by which the mental impression becomes palpable, being in every case nervous structure. The nervous adaptation is, in one respect, to the intellectual type or idea, as wax to an engraved type, or as the prepared recipient to the calotype. The recipient of an emotional type, like the retina, merely reflects the impress of the appropriate agency. Hence, the emotions are not inherent in the region where they are usually felt. During the absence of their corresponding types or ideas the nervous media of manifestation are as blank as was this paper before the compositor made it significant. So soon as the emotional type or idea appears in the mind, the nervous adaptation takes it up and expresses it; in other terms, renders an emotion palpable. But as the presence of any idea or type is altogether dependent on a human volition, and cannot be present or absent except the mind so wills it, so every emotion, being merely the consequent of its corresponding idea, can only be present or otherwise as its intelligent cause, however unwittingly, shall have given the fiat. Hence, the

secret of self-government. Hence, also, the power of example, and the assimilation of character in childhood and at other periods of life. Hence, the remarkable expressions of tragic and comic art. Hence, even the phenomena of what is nicknamed Measmerism. We suspect also that forms of insanity are much more dependent on this extraordinary law of emotional existence than physiologists may be disposed to believe. If Dr. Davey has witnessed 'in one individual,' under what he calls 'magnetic excitement,' 'more forms of monomania than he has ever seen within the walls of Hanwell,' and these 'so splendidly illustrated that he doubted whether the reality could have excelled them,' physiologists have yet much to learn respecting the power of a dominant idea, conception, or phase of mind, in relation to that particular condition which is at present termed insanity."

Mr. Harney.—We are afraid the party is a beguiling-letter impostor. Having succeeded with ourselves and one or two others, he seems determined to follow up the vein. We are far from recommending the applicant. The same note for 30s. on the plea of "redeeming clothes from pledge" was our tribute.

We are obliged to Mr. Watson for his obliging transmission of the report.

Ostrick.—We know of no such physiological miracle. In the only case we know of, where a knife was swallowed, death speedily followed. Men, it has been said, may by habit swallow marbles with impunity—not knives.

Dr. Torbeck's case in our next.

We really do not see the force of the authorized contradictions to the views expressed by our correspondents on the Birkenhead case. The jury may meet and vote themselves quite right—and nobody ever charged them with thinking too little of themselves—but the main facts remain as they were—very much against them.

M. P. II.—Mr. Payne's custom of holding inquests after every case of suspicious fire is not well suited for comment in our journal. Of course every coronor should do the like.

Ch.—The long letter on John Hunter's monument is rather too personal for publication.

Our correspondent Galen, who rails at what he calls parallel novelties—M—H—, and his discoveries—would only tell a thrice-told tale by the publication of his letter. If "the ambitious rascal" be burning out—and hence a little additional stir and fume," the less we should care about diffusing the bad odour.

We have received several letters and communications which will be noticed next week. Among many we have to acknowledge the following:—Dr. Hollis, Yarmouth; Mr. Wildash, Canterbury; Mr. Wigginton, Wadhurst; Mr. Fraul, Arbroath; Mr. Monckton, Brackley; Mr. Joy, Maidstone; Mr. Davies, Pershore; Mr. Irving, Lockerbie; Mr. Turner, Kendal; Mr. Stuart, Dunse; Dr. Wallace, 76th Regt.; Mr. Markwick, Langham-place, Dr. Willskire, Cowl-street; Mr. Smith, King's College Hospital; Dr. Wright, Birmingham; Dr. Palmer; Mr. Braid, Manchester, &c.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the SCIENCE of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their use; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no

listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract love of a pedantic and inapplicable lore. Every power of his mind is engaged; he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate, to be EXERCISED: each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diploma or license.

Six of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is *bona fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, APRIL 10, 1847.

STATE OF MEDICINE IN ENGLAND.

THE trial, or rather the triumph, of Dr. Denis Cronin came off on Wednesday last. The learned gentleman had only to look at the judge and jury to get his acquittal, which—the public reciprocating the sentiments of the court—we are told by the newspaper report, was received with loud cheering.

The circumstances of the trial have an insignificance quite proportioned to the importance of the facts of the case; and the fair conclusion to be derived from them is, that Dr. Cronin, in being the unhappy instrument of the death of his unfortunate patient, ought never to have had a moment's uneasiness on his legal responsibility for that calamitous result. Denis Cronin may practise by the dozen, Miss Colliers may die by the hundred, and the law of England, as it at present stands, has nothing in waiting but acquittals, cheers, and triumphs for the lucky agent.

The details of the trial, in another column, have a sort of designed tendency to bring the administration of justice into contempt. The facts brought before the court were, probably, the very facts of least consequence in the case. The witnesses examined were exactly those whose knowledge least revealed the merits of the case. The witnesses kept back and not heard were precisely the gentlemen who, if there were any case at all, could have alone established it. In short, from the selection of Dr. Cronin as physician, to his acquittal by the jury as a prisoner, there seems, as by a fatality, to have been no incident in the whole tragedy which, as influenced by the law of this country, can provoke any opinion, save one of censure and indignation.

In the beginning of February a young lady of large possessions, in the prime of life, and, with the exception of some slight leucorrhœa, apparently in the most perfect health, was imprudent enough to aim at lightening the *tedium vitæ* by consultations with a physician whose consumptive trophies had been bla-

zoned forth, in unacknowledged advertisements, through most of our general newspapers. Before she had acquired the luxury of more than two visits, at the expenditure of the moderate sum of one guinea, she paid the penalty of her foolish restlessness, and offered for the tablets of Esculapius another inscription like that of the honest tombstone:—"I was well, and was not satisfied: took physic, and died." On the first visit the physician condescended to make up his own prescription, and by this accident was saved some bad Latin on his part, and, for a time at least, *life* on that of his interesting patient. On the second occasion the gentleman was more orthodox professionally, and less successful practically—a coincidence less uncommon than is probably imagined.

He wrote out his prescription *secundem artem suam*, and, exemplifying at least one honourable distinction between himself and some prescribing practitioners we have heard of, left it to be dispensed by *any* druggist his patient might like to choose. The following was his recipe:—

"Rx.—Spt. ammon. arom. ʒij.; tinct. opii M. xvj.; acidi prussici (Scheele's) gtt. iv.; pulv. strychn. comp. gr. ij.; aquæ amygd. amar. ʒij.; fiat mist. e qua sumatur. coch. ij., ter in die.—Feb. 3, 1847.—Miss Collier.—D. C."

We must in charity imagine that Dr. Cronin aimed at giving a new illustration for the chapter of chemical decompositions. It would seem as though the learned doctor sought to make potencies inert, and out of many energetic medicines to get the effect of none. In disguise—apart from the one ingredient, the cause of the calamity—the French expectant system seems anxiously looked after, under the disguise of the most energetic English treatment. Judging from this single instance, we should say there is no more expert artist in the kingdom for "pouring ingredients of which he knows little into bodies of which he knows less." If there were no tragedy connected with the prescription it would justify endless cachinations from every medicinal tyro in civilized Europe.

It is obvious that a blunder of the greatest magnitude is committed, in the vague way in which we have bitter-almond water prescribed. On its absence from the Pharmacopœias we make no complaint; though illegal, there is no physician who confines himself to the preparations of the three Pharmacopœias; to do so, indeed, would be to show greater confidence in the three colleges than we entertain, and practically to put a stop—in one department at least—to the progress of medicine. But Dr. Cronin, in using his new and extraordinary remedy, ought to have been aware of the circumstances of its preparation and sale. If he were ignorant of these, he was dealing with a deadly agent, with a culpable unacquaintance with its qualities. There was no justification for such ignorance, and for every calamitous result arising from it he was morally, as well as legally, responsible. If he were unacquainted with the nature of the drug he prescribed, or of the circumstances of its preparation and sale, there is no excuse for the evident peril which his mode of prescribing it necessarily involved. He prescribed what, in many of its forms, must inevitably have

killed his patient, and had no protection against that catastrophe but qualities in the druggist on which this case too clearly proves he ought not to have counted—discretion, intelligence, and science.

But this improper reliance on the druggist did not end here: the prescription actually containing three points of difficulty on which any druggist would be left at sea for a solution. The compound strychnine powder, by that description, is one of the most indefinite preparations a druggist could have to deal with. Dr. Cronin tells us that he meant a simple compound of sugar and strychnia; but no such preparation is recognised in any pharmacology that we are acquainted with. The only one authorized at all is a totally different composition; and then, finally, as if the vagueness of the almond-water was not of itself sufficiently perilous, we have a total omission with regard to the amount of the dose. A spoon, is mentioned preceding the doctor's initials; the size is wholly omitted. Thus it was a prescription which no man in his senses ought to have written; and thus, too, was it a prescription which no man out of bedlam ought to have dispensed.

Mr. Corfield, of High-street, Camden-town to whom the prescription was first brought knew nothing of the compound strychnia, nor of the almond-water, and had neither in his possession. How does he aim at supplying the defect? He sends to Mr. Morson. Mr. Morson, who is a vice-president of the Pharmaceutical Society, seems to have had neither preparation, and little, if any, knowledge of them. Mr. Jacob Bell is next applied to, who sends a private form for the compound strychnine powder, and twelve ounces of almond-water, an ounce of which represents, he tells us, sixty-one (seventy?) minims of the Pharmacopœia prussic acid. Mr. Bell—the editor of a Pharmaceutical Journal, the founder and ruler of a Pharmaceutical Society—though he knew that Continental Pharmacopœias showed eighteen different varieties of bitter-almond water, all varying in strength, from comparative inertness to a proportion in which one ounce will equal sixty-one minims of prussic acid, sends a brother chemist twelve ounces of this fearful liquid, in this strongest form, without marking the preparation as poisonous, or defining its strength! Of the eighteen preparations known to Mr. Jacob Bell, the chemist Corfield was left to speculate whether the preparation was the weakest number one, or the strongest number eighteen; and thus provoked and partly justified Mr. Corfield in the supposition that it was an innocuous preparation, requiring no extraordinary care.

The prescription—which had thus first a blundering origin, then encountered pharmaceutical ignorance on the part of a vice-president of a Pharmaceutical Society, and then is blunderingly dispensed by a founder of that society—now meets its *finale* of blunder from Mr. Corfield, who, we believe, is a member of the same learned society. Knowing nothing of the strength of the concentrated poison sent to him by Mr. Bell, he unhesitatingly purveys

it in a dose that must necessarily kill the patient; he just as unhesitatingly slurs over the difficulty as to whether the spoonful of the poison ought to be large or small; and, having no compound strychnine powder, he coolly makes up the prescription without it, although a formula for its preparation is at that moment in his hand!

The poor girl takes the poison and dies almost immediately. The blunder of her physician and her druggists had brought on her, in the midday of life and health, a crisis which neither the strength of her own constitution, nor the scientific skill of Mr. Weathers, could carry her through. She perished a martyr to a bad state of physic, and, if possible, a worse state of pharmacy. Would that we could say that she was the only victim!

• Before indulging in the general remarks which this dreadful case naturally suggests to us, we must be allowed one word on the defeat of justice which this trial so strikingly manifests. From the moment we had read the details of the inquest we were quite certain what would be the issue. How could a jury or the public connect fairness or value with a coroner's proceedings, when the parties who were little, if at all, less blameless than Dr. Cronin, were brought forward against him as applauded and unexceptionable witnesses, and when, above all, Jacob Bell, who had so largely contributed to the fatal result, was empowered to make a scientific analysis of the poison actually supplied by himself? A more extraordinary procedure we cannot conceive; and if Mr. Jacob Bell is, has been, or is expected to be, as the founder of pharmaceutical societies, in relation with that coroner as a member of Parliament, in reference to the question of medical reform, and its adjustment to suit pharmaceutical interests—if Mr. Jacob Bell shall be found, as the editor of "The Pharmaceutical Transactions," acting in concurrence with that coroner as a journalist, the public will not be slow in demanding on what grounds of public policy so anomalous and so suspicious an appointment was made.

Mr. Bell enters on the analysis in the laboratory of the Pharmaceutical Society. The coroner—fair enough to entrust—he sufficiently delicate to accept—the disposal of the fate of his copartner in misfortune—Dr. Denis Cronin, what, do our readers think, were the media by which this eminent chemist sought to ascertain whether or not more than four drops of Scheele's prussic acid—yielding a precipitate of cyanide of silver of say $\frac{1}{100}$ part of a grain—were contained in a six-ounce mixture? Scales made for pounds, but which *could* turn with a grain! and a pair of dispensing scales which would turn, *perhaps*, with the twentieth of a grain!—but no weights smaller than tenths being forthcoming in this Royal Pharmaceutical Society, even this quasi-delicacy could not be ascertained! The scales, of course, had no glass case; and we were informed by an eminent chemist present, that, though every instrument necessary for so minute an investigation was absent, Mr. Bell and Mr. Morson, both great authorities in the world of pharmacy, would in-

dict—notwithstanding the delicate responsibility under which they were acting—that the apparatus would "afford results that were near enough"!

Placed in such hands, we can condole with even Dr. Cronin; but what shall we say of British pharmacy condemned to no better protectors! The Pharmaceutical Society affects to be the head-quarters of practical chemistry in this country. Mr. Morson is one of its presidents, Mr. Bell has the higher honour of being its founder and literary exponent. If we may judge of the chemical attainments of other functionaries of the body from those manifested by the leading duumvirate, we should say that this pharmaceutical congeries would be just as appropriately designated if called "The Astronomical Society." It is impossible that they can know less of one science than of the other.

MISCELLANEOUS CORRESPONDENCE.

HOMŒOPATHY.

[To the Editor of the Medical Times.]

SIR,—The discussion on the subject of homœopathy to which, with your usual liberality, you have opened your valuable pages, and more especially the remarks of Mr. Close in your number of Saturday last, have induced me to trouble you with the following observations. I must premise, however, that I do not present myself as the advocate of homœopathy, my experience in the science having been too slight to enable me to enter the lists against those who regard it as based upon unfounded principles; but, leaving its advocacy to others, I do not hesitate to affirm that, in my judgment, the propositions of Dr. Hübner have not been at all affected by the arguments of his opponents. On the other hand, orthodox physic not unfrequently receives a side-blow from the unconscious hands of its own supporters, and I am inclined to believe that many of the remarks in Mr. Close's paper are as fatal to allopathy as to homœopathic doctrines:—"Gravitation, electricity, and magnetism," observes he, "are general laws which coexist with, and depend upon, the integrant constitution of bodies themselves; so likewise the healing law, it may, *a priori*, be anticipated, should be sought for, and will be found, in the organic construction of the living being itself, and not in the extrinsic material which may be brought to act upon it. This law has been long recognised as the *vis medicatrix*, and not the *similia similibus*. To watch, to assist, to control its operations, make up the sum of the true philosophy of medicine."—"In some instances it succeeds partially, in others it fails; in some it seems to act too powerfully, and, like the viper, inflicts upon itself the sting of death. In all, under circumstances favourable to observation, its benign influence may be more or less recognised."

Now, Mr. Close, in attempting to indoctrinate his readers into the assumed connection existing between the healing law and the general laws of matter, should at least have taken care to instruct himself fully of the nature and properties of the latter. The general physical laws, gravitation, electricity, &c., do not "depend on the integrant constitution of bodies," they coexist with matter itself, and are inherent in its minutest atoms as well as in its largest masses; and thus, starting with a false fact, he runs into the false assumptions and hasty generalizations of which he, I think rather unfairly, accuses his opponents. What can be more absurd than the figurative representation of a *vis medicatrix* inflicting upon itself, viper-like, the sting of death? If there exists in the living organism a power or quality which enables it to remedy its lesions, according

to a law as unfailling and unchangeable as the laws which govern the phenomena of inert matter, it appears to me contrary to all analogy to suppose that the great Author of nature would permit the operation of that law to counteract the benign intention with which it was so wisely framed. Again, if such an innate power exist, I much fear that few of our allopathic forms of treating disease can be considered as adjuvants to its operations: when, for instance, we apply leeches, blisters, &c., to the abdominal surface in peritonitis, we can hardly be said to be aiding the operations of the *vis medicatrix*, which is lavishly pouring into the membrane an excessive quantity of blood, while we are endeavouring most strenuously to induce its metastasis by the action of powerful derivatives. It appears to me that it is only in the healthy healing process succeeding a disease, or the infliction of a wound, that we witness anything which can be positively affirmed to be an inherent sanatory process, or *medicatrix* of the organism. We know that a wound will heal, or a solution of continuity in bone be repaired, by vital processes, provided the surrounding tissues be healthy: for there appears to be a wide distinction between a traumatic and an organic lesion, although organic disease may be evoked by a simple wound under peculiar circumstances; but in both instances the efforts of the system appear to be evidently reparative or reconstructive, not antagonistic. When the seeds of a disease have found a *nidus* in the system, it will surely run its course if not checked by the action of what Mr. Cose would call "extrinsic material;" and if the constitution of the patient, aided by idiosyncrasy, and perhaps by the action of medicinal agents, is capable of withstanding the disease, then the action of the *vis medicatrix*—that is, the constructive or reparative action—is observed to progress with rapidity under favourable circumstances, until the injured tissues are remodelled or built up; their constructive perfection constituting health. In this view of the question, which I believe to be the correct one, the organism presents but a passive resistance to the encroachments of disease, and the action of the *vis medicatrix* is purely reparative and reconstructive. Disease we unfortunately know but little of, irrespective of the symptoms it produces; pathology exhibits its ravages in particular organs, but with regard to its origin our hypotheses are of a very unsatisfactory nature; and the same may be said of the action of remedies in subduing or eradicating it. Indeed I much fear that most practitioners would be induced to echo the affirmation of the late Dr. J. Johnson, at the close of his professional career, to the effect that, in the exhibition of remedies, he believed he had done more harm than good.

As an independent and unprejudiced reviewer of the arguments between the advocates and opponents of homoeopathy, I must say that I do not think that its opponents have bestowed sufficient attention on the subject, nor do I think that Mr. Cose discusses the question with due fairness. "Facts," observes he, "are the only basis of accurate knowledge, though not in themselves sufficient without collation and comparison with themselves, and with general laws." Now, leaving the grammatical accuracy of the above sentence out of the question, I am inclined to believe that its logic is scarcely sufficient to warrant us in placing implicit reliance on the powers and judgment of the writer, for if facts are the only basis of accurate knowledge, they should be in themselves sufficient. Again, his assertion that the opponents of homoeopathy are bound by the *ipse dixit* of a person who half a century ago experimented with certain drugs, is unfair and erroneous, for he must be aware, if he has studied the subject, that it is not to the experiments of a single individual he is bound to give credence, but to those of a great number, both contemporaries and post-temporaries of Hahnemann. Nor has it ever been asserted, that I am aware, that homoeopathic doses of belladonna have ever produced a scarlet rash, or homoeopathic cinchona the ague. Why, then, resort to the miserable shift

of a *petitio principii*, when the real question is within reach? It would be extremely easy to prove, by a reference to the writings of Hahnemann and other homoeopaths, that the effects of the medicines used in homoeopathy have been tried in almost the usual allopathic doses, the minute doses having only been employed as the result of gradual experience in the treatment of disease. It is not at all improbable, indeed it is only ignorance or obstinacy that will lead medical men to sneer at the fact, that, in particular states of the system, certain medicines will act more powerfully than usual, and *vice versa*. The 12th of a grain of tartar emetic will produce violent emesis in an individual usually unaffected by twelve times the dose; and I have frequently seen it administered to infants in croup to the extent of three or four grains in divided doses, within a quarter of an hour, without producing even apparent nausea; and calomel may sometimes be given in enormous quantity, as in acute inflammatory attacks, cholera, &c., without inducing its usual effects. Again, some there are who can bear the strongest and most repulsive odours with ease, while some may

"Die of a rose in aromatic pain."

These are facts bearing, as they do, so strongly on the subject of idiosyncrasy, that the truly interested explorer of medical science will not be inclined to slur over with a pshaw! or dismiss with a sneer. Who knows not that peculiar constitutions are more susceptible than others of the action of particular medicinal agents? or that at one time the system will become affected by a dose much more minute than will ordinarily tolerate?

Indeed the doctrine of pathogenesis, as introduced by Hahnemann, is of a deeply interesting character, and in a physiological point of view may lead to the most important discoveries.

If in the *argumentum ad hominem* "fair play is a jewel," in the discussion of subjects connected with science, and, above all, medical science, it is indeed a jewel of infinite worth. The avenues to the Temple of Truth are effectually guarded against the footsteps of prejudice, bigotry, and intolerance. We should enter the fields of research with a desire to aid and not oppose each other in our scientific explorations; by such means alone the progress of science will be advanced, while, on the other hand, it must be most certainly retarded by the antagonism of conflicting interests, and the brawlings of party strife. It appears to me strange indeed that not one of the opponents of homoeopathy have essayed to repeat the experiments on which its law is said to be founded; and although I think I hear Mr. Cose exclaim, "Sophistry! mere sophistry!" every sensible person will at once acknowledge that such is the only mode by which the presumed law may be either negatived or affirmed. This may be sophistry in Mr. Cose's logic, but it would be difficult to find a parallel for such a sophism in Bishop Whately's.

Let the science be submitted to a tribunal of men of acknowledged abilities; let its principles be subjected to a fair and impartial analysis, and judgment be pronounced accordingly; but its advocates may congratulate themselves, thus far at least, that it must be rather advanced than retarded by the writings of opponents who seem to know but little either of its principles or practice.

I am, Sir, your obedient servant,
TRUTHSEEKER.

London, March 15.

TRIAL OF DR. CRONIN FOR THE MANSLAUGHTER OF MISS COLLYER.

[Before Mr. Justice Coleridge.]

Dennis Cronin surrendered to take his trial at the Old Bailey, on Wednesday, upon an indictment charging him with the manslaughter of Sarah Ellen Collyer.

Mr. Payne prosecuted; and Mr. Clarkson conducted the defence.

Mr. Clarkson said that he should not attempt

to dispute the facts connected with the death. It would only be necessary to state that the deceased was suffering from some malady at the commencement of last February, and applied to the defendant, who furnished her with some medicine, which was sent from his own dispensary, and after she had taken it she appeared better. The defendant afterwards gave her a prescription, telling her that she could get the medicine made up at any chemist's, and it appeared that on the 16th of February a person named Johnson was sent with the prescription to the shop of a druggist named Corfield, in Camden-town, and he received from him a bottle of medicine, which he brought back to the deceased, and upon her taking a tablespoonful of the mixture she immediately complained of illness, and died in the space of a very few minutes, the death being clearly occasioned by prussic acid contained in the compound thus furnished.

Mr. Daniel Corfield was examined: He deposed that he was a chemist, and resided in High-street, Camden-town. He remembered Mr. Johnson coming to his shop on the evening of the 15th of February with a prescription for a mixture, which was to be composed of two drachms of compound spirit of ammonia, sixteen drops of tincture of opium, four drops of prussic acid (Scheel's strength), two grains of compound strychnine powder, and six ounces of bitter almond water. The prescription was dated the 3d of February. Having no strychnine powder or bitter almond water, he sent his boy to fetch some, and he brought back a 12 oz. bottle of bitter almond water, and having placed the other ingredients in a bottle, with the exception of the strychnine powder, he filled it up with six ounces of the bitter almond water, and gave the mixture to Mr. Johnson. In addition to this evidence, he stated that, having been in business as a chemist for twelve years, he never before heard of strychnine powder or bitter almond water being used as the ingredients of medicine.

Cross-examined: He was entirely ignorant of the qualities of bitter almond water and strychnine powder, and they were not named in any recognised Pharmacopoeia. The last edition of the "Pharmacopoeia" was published eleven years ago; and since that period there had no doubt been a great advance of medical science, and many new discoveries in medicine had been made.

Mr. Clarkson: Do you know anything of the character of strychnine powder, or whether it would be calculated in any way to neutralize the effect of the other ingredients of the mixture?—Witness: I don't know anything of the quality or effect of this powder.

Mr. Clarkson: And yet you did not communicate the fact of its having been omitted to the party to whom you gave the medicine?—Witness: I did not.

Mr. Clarkson: In justice to Dr. Cronin, will you tell us whether you sent the prescription to Mr. Bell, from whom you obtained the bitter almond water?—Witness: I did not.

Mr. Clarkson: Then he had no means whatever of knowing how it was to be used—whether internally or externally?

Cross-examination: The bitter almond water appeared only to be intended as a medium for mixing the other ingredients and making up the quantity. The different articles mentioned in the prescription he should say were calculated to neutralize each other; the spirit of ammonia, for instance, would decompose the prussic acid. He was not aware that there were a great many different descriptions of bitter almond water, and that some were deadly poison while others were perfectly harmless. It was evidently the intention of the prescription that the simple bitter almond water should be used, and not the concentrated essence of the bitter almond, and then only as a vehicle for mixing the other ingredients.

Mr. Clarkson: And you filled up the bottle with six ounces of deadly poison?—Witness: I filled it up with the bitter almond water that I received from Mr. Bell.

Mr. Clarkson: Without meaning anything offensive, will you allow me to ask you whether persons who follow the profession of a chemist undergo any medical examination?—Witness: They do not.

Mr. Justice Coleridge here interposed, and observed, that to say the least of it the act of pretending to make up a prescription sent by a physician, without putting in all the ingredients mentioned in it, was most monstrous. Although not a fraud in the ordinary sense of the term, still it was one on the person for whom the medicine was intended. Such a proceeding was very dangerous in any case, and he was not prepared to say what the effect had been in the present instance.

Mr. Morson, a chemist in Southampton-row, to whom the first application was made by Mr. Corfield's messenger for the powder and the bitter almond water, but who not having them referred him to Mr. Bell, of Oxford-street, was next examined, but he merely proved that, having been in business as a chemist for a great many years, he had never heard of bitter almond water being used in compounding medicine.

Mr. Jacob Bell deposed that he received an order from Mr. Corfield for the bitter almond water and the strychnine powder. He had none of the powder, and therefore he only sent the bitter almond water, and a formula of the powder that he found in a book to which he referred. There were twenty-two different descriptions of bitter almond water, and looking at the prescription he should not know what description was required, and if such a prescription had been sent to him he should not have made it up without communicating with the physician. Different distilled waters were made use of to mix medicine in, some being poisonous and others harmless; but in the former case he should expect the prescription would denote the strength that was to be used. Chemically speaking, he was of opinion that the omission of the strychnine powder would not at all affect the quality of the mixture in question, excepting that the omission of a poisonous ingredient would have rendered it less poisonous. This powder was a preparation from *nux vomica*, but the quantity mentioned in the prescription would in itself have been perfectly harmless.

Cross-examined: If he had seen the prescription he should have known that the bitter almond water was merely intended as a vehicle for the administration of the medicine, and he would have made use of a harmless description of bitter almond water. In that case no mischief would have happened. He had no means of knowing whether it was to be used internally or externally, or, in fact, to what purpose it was to be applied. If he had known that the bitter almond water he sent was to have been used internally, he should not have put the word "poison" upon the bottle, because he should think a chemist would be aware of the fact; but if he had known that he was dealing with a person who admitted, although in that profession, that he was entirely ignorant of the qualities of the article, then he should certainly have put the word "poison" on the bottle. The article he sent was a concentrated bitter almond water, but there was some of a more powerful description.

Mr. Justice Coleridge inquired of the witness whether, when the chemists sent out the concentrated almond water, it was not customary to label it as such?

The witness said it was not customary to do so. In answer to further questions put by Mr. Clarkson, the witness said that although he did not consider the quantity of bitter almond water that he sent was sufficient to kill a horse, there was quite enough to destroy a human being. He likewise said that there was no doubt the physicians of the present day were infinitely in advance of the existing Pharmacopœia.

Re-examined: In his opinion the prescription should have denoted the strength of the bitter almond water that was to be made use of.

Mr. J. E. Spratt, chemist, deposed that he kept five descriptions of bitter almond water—two English and three foreign. He was in the habit of making up physicians' prescriptions, and constantly used bitter almond water. If the word "concentrated" was not mentioned in the prescription he should use the strength stated in "Gray's Pharmacopœia," which would be quite harmless.

Mr. Justice Coleridge: Then, in your opinion, the omission of the word "concentrated" was an indication that the weak description of bitter almond water was intended to be used in the prescription?—Witness: Certainly. If this prescription had been sent to me I should have used the weak compound.

Mr. Justice Coleridge: And if you had done that would the mixture have been harmless?—Witness: I conceive so.

The learned judge here inquired of Mr. Payne whether he thought the case ought to be carried any further?

Mr. Payne said he certainly thought after the evidence that had just been given that the matter was too doubtful to justify a conviction.

His lordship observed, it appeared perfectly clear that a chemist possessing the ordinary knowledge of his profession must have known that a weak description of bitter almond water was intended to be used for the prescription. Mr. Corfield did not appear to have known anything upon the subject, and he did not give the prescription a fair chance.

The jury then deliberated together for two or three minutes, when

Mr. Clarkson observed, that perhaps it would be more satisfactory to all parties that another medical witness should be examined.

Dr. Robert Venables, lecturer on forensic medicine, was accordingly called, and, after having stated that upon analysis he discovered sufficient prussic acid in the liquid of which the deceased had partaken to account for her death, he said that, looking at the prescription, he should have expected that the ordinary weak compound of bitter almonds would have been used, and that was perfectly harmless. He also said that if the strychnine powder had been added, although it would not have had any chemical effect, it would have acted physiologically upon the system, and would have had a similar effect to ammonia in neutralizing the prussic acid.

The jury here interposed, stating that they were quite satisfied with the evidence that had been adduced, and they at once returned a verdict of *Not Guilty*.

Mr. Clarkson observed, that if the case had gone further he had twenty chemists present to prove that bitter almond water was constantly an ingredient in the prescriptions they made up for physicians.

Mr. Justice Coleridge ordered the defendant to be immediately discharged.

DR. CRONIN'S TRIAL AND ACQUITTAL.

(From the *Pharmaceutical Times*.)

SINCE the late calamitous death by prussic acid—an occurrence which, bowing to judicial authority, we may no longer call manslaughter—we have been inundated with letters in some way relating to the principal hero who figures in the tragic scene. Of course we did not notice these communications, considering it but just to Dr. Cronin, that our opinion should be reserved until after the judicial inquiry had terminated. We were determined, in other words, not to prejudice his case; and, therefore, offered no opinion on the nature of certain prescriptions which had reached us under the signature of D. C.; much less did we oblige our correspondents by ascertaining whether this same Dr. Cronin was the individual who had already been implicated in one charge of manslaughter at Liverpool, and another at

Barnstable. Indeed we were rather favourably disposed to the doctor, who appeared to us an honest man, performing what his advertisements promised—to cure consumption. In truth, few diseases, we believe, would resist the heroic treatment of *nux vomica* and prussic acid which seems so peculiarly his own. But, reverting to the prescription which caused the death of Miss Collyer, let us coolly and dispassionately ascertain, if we can, what the doctor really meant to be dispensed.

Unquestionably his prescription was fatal on account of the large amount of prussic acid ordered; chiefly in the form of bitter almond water; and the trial seems to have broken down in consequence of the assumption that the bitter almond water mentioned in "Gray's Supplement to the Pharmacopœia" ought necessarily to have been employed. Why necessarily we cannot tell, inasmuch as "Gray's Supplement" is not a recognised guide for the preparation of medicines; and it is not incumbent on any dispenser of medicine, he be apothecary—be he druggist—to be acquainted with any form therein contained except such as may also exist in the Pharmacopœia. But, did Dr. Cronin ever intend to have employed the formula mentioned by Gray? would the patient have been supplied with this form in her mixture had she procured it from Dr. Cronin's own shop? Undoubtedly not; for we are informed by Mr. Venables, a pupil of Dr. Cronin's, and son of the Dr. Venables who was the only medical witness examined at the trial, that the bitter almond water used by his principal was a very dilute preparation, made by adding a few drops of bitter almond oil to a large quantity of water. After all this importance, then, which has been given to "Gray's Supplement," as a recognised standard for the dispensing of medicine, it happens that, even had the prescription been dispensed in accordance with this book, the almond water would not have been that intended by the prescriber—there would, in fact, have been committed, in one sense, a *mistake*, and the young lady's life might have been saved. We say, might have—for, unquestionably, the bitter almond water of Gray is far from being the harmless compound asserted by Mr. Spratt—in fact, it is a poison.

Again, as to the compound powder of strychnia. After the fatal prescription had been dispensed, and the young lady's death had taken place, the compound powder of strychnia mentioned by Beazely was fixed upon by Dr. Cronin, and his friendly advocates, Mr. Tennant and Dr. Venables, as the basis of another special pleading.

The preparation in question contains black oxide of iron, a fact eagerly laid hold of by Dr. Venables, the chemical adviser of Dr. Cronin, to be wielded in the following line of argument:—"That had the compound powder in question been used, prussic acid would have been formed, and hence a portion of the prussic acid rendered inert. It would seem, then, from the tenor of this argument that Beazely's compound strychnia powder was the substance intended by the prescriber,—that a mixture coming from his shop, and dispensed in accordance with the aforesaid prescription, should have displayed a blue colour:—not so again—for at a more advanced period of the inquest the doctor admits that his own compound powder of strychnia did not contain oxide of iron! hence all that had previously been advanced about the neutralizing effect of that oxide and the blue mixture was merely an example of *ex post facto* ingenuity, the honesty of which our readers can appreciate. Even had black

oxide of iron been present, we need not tell our chemical readers that it would not have formed prussian blue with hydrocyanic acid, and that the neutralizing effect spoken of is purely imaginary. We waive altogether the absurdity of supposing that the third part of a grain of either of the iron oxides would have materially weakened seventy minims of pharmacopœial prussic acid. We certainly blame Mr. Corfield for having omitted the compound powder,—but merely on the general ground that a druggist has no right to tamper with a prescription;—in this case its addition would have increased the poisonous nature of the mixture.

Dr. Cronin cannot complain because we judge him by the standard, which he and his judicial friends have laid down for his own guidance. It has been argued that Gray's formula for bitter almond water and Beazley's formula for compound strychnia powder, should have been employed. The public have been amused by recitals of the various chemical reactions, and physiological antagonisms, which would have resulted had they been employed; and yet—after all this display of scientific argument—the preparations in question were never intended to have been employed at all!

Were it our province to expatiate on the general incongruity of materials indicated by Dr. Cronin's prescription, our task would be long indeed. Never had we seen any previous instance of such deadly materials so intermixed;—with a playful wantonness, it would seem, and to accomplish no definite object whatever. An idea seems to be prevalent amongst the public—and we are not wrong in saying that it is encouraged by the doctor—to the effect that the compound spirit of ammonia used counteracted the prussic acid. Now, this assertion is neither chemically nor physiologically correct. The union of the two would form hydrocyanate of ammonia, a substance nearly as virulent as prussic acid itself, as the experiments of all toxicologists will testify. True, if hydrocyanic acid be swallowed, ammonia is employed remedially;—not chemically, but as a stimulant; which stimulant effect is, of course, lost by union with hydrocyanic acid.

True it is that hydrocyanate of ammonia is somewhat more liable to decomposition than hydrocyanic acid itself; but to what extent has been proved by a comparative analysis of Dr. Scoffern, performed by the coroner's order. After a lapse of more than a week, the fatal mixture, on being analyzed, was found to contain only four hundredths of a grain of prussic acid per cent. less than a similar mixture prepared at the time of analysis.

Having directed the foregoing remarks more particularly to Dr. Cronin and his prescription, we will now say a few words on the mode in which the judicial inquiry was conducted. It will be considered strange by many parties that no counsel for the prosecution was employed by the friends of the deceased. The death of a young, and, we may say, healthy, girl, by prussic acid, would have been sufficient to have aroused, in the breasts of some relatives, feelings of deeper resentment than seem to have been exercised in the present case. Various reasons for this seeming forgiveness have met our ear, but with which it is not our province to meddle; the result was, however, that no counsel for the prosecution was appointed by the friends of the deceased; therefore the depositions were read at the request of the court by Mr. Paine.

The mode of examination of witnesses pursued was, no doubt, in accordance with legal propriety, albeit many points require explana-

tion to us. In the first place, it does appear to us extraordinary that the medical gentleman, Mr. Weathers, who was at the eleventh hour called in to see the unfortunate young lady, did not grace the witness-box at all;—that the only medical witness examined was Dr. Venables, whose son was, and, we believe, still is, a pupil of Dr. Cronin's; that Mr. Clarkson, for the defence, after getting Mr. Corfield to admit the total incompetency of druggists (we think Mr. Corfield was unjust to his class) to give a chemical opinion—actually, after this admission, sought all the chemical testimony he required from Messrs. Bell, Morson, and Spratt, members of the class whom he had inferentially accused of ignorance in that particular science, to the exclusion of Dr. Scoffern, who, although he had performed the analysis by the coroner's order, and therefore was certainly an important evidence, was excluded the witness-box altogether! We felicitate Dr. Cronin on having had so important a witness as Mr. Spratt, the gentleman who at the coroner's inquisition was blessed with so oblivious a memory, but who, in the lobby of the Old Bailey on the morning of the trial, stated exultingly that he did remember, but would not be fool enough to tell! This same Mr. Spratt, one of the class on whom the counsel for the defence had inferentially thrown a doubt as to their amount of chemical information, affirmed that Gray's bitter almond water was harmless, and that he should have used it; on which the case broke down.

And now a passing word for Mr. Jacob Bell. He—the well-meaning regenerator of British pharmacy—the patron of the Pharmaceutical Society—to send out a deadly poison without a label! and—although cognizant of “twenty-two varieties,”—without one word to indicate that this was THE MOST POISONOUS! Shame! We can imagine him on the far-away sheriffs' bench glancing with unquiet eye towards the felon dock, conscience whispering that which we yesterday heard more audibly expressed, that he, too, should have been there!

One important consideration still remains to be discussed—the amount of responsibility which society attaches to dispensing chemists. It appears, then, from a consideration of this case, that society is not content to regard them as mere dispensing machines: they are expected to be competent to pass a judgment on the general qualities of a medicine, and to be equal to the task of detecting any glaring mistakes. This is what society requires of them—will have of them; and yet the law inferentially brands them as incompetent! Now, how much longer will dispensing chemists submit to this aspersion? How much longer will they remain disconnected among themselves,—lost to the sense of their own rights,—treated with distrust by society, and be made to pronounce their own dishonour before an Old Bailey jury?

Unquestionably, the education of druggists in general has been felt by themselves to be under the mark which the exigencies of their calling require; these deficiencies they have themselves denounced, and have expressed their wish to overcome; but they have built their faith, and it is with grief we say so, on what promises to be a foundation of sand—the Pharmaceutical Society!

The greatest social and educational boon which the druggists' assistants could have acquired—a few hours for educational purposes in the evening of each day—has been systematically refused by the society, under the absurd plea that the assistants would become immoral thereby. Much more likely is it that a

few's peculiar interests have been consulted in this matter,—and that, for the peculiar benefit of them, a whole community has suffered! But we have said enough; the Pharmaceutical Society was either made for the body of druggists, or they were made for it,—which supposition is the correct one the druggists themselves must decide.

CHARGE OF POISONING BY ARSENIC.

NORTHERN CIRCUIT—MARCH 30.

[Before Mr. Baron Alderson.]

Elizabeth Johnson stood charged with the wilful murder of Henry Johnson, at Barton-upon-Irwell, by the administering of arsenic.

Mr. Hulton, Mr. Monk, and Mr. J. Pollock for the prosecution. The prisoner was defended by Mr. Sergeant Wilkins and Mr. Overend.

The facts for the prosecution were as follow:—

Robert Johnson stated that he was the brother of the deceased, who was forty-two years old at the time of his death. Had never known the deceased ill in his life. Was present when the body was disinterred, on the 9th of March. Mr. Hepworth and Mr. Lee were present. The deceased kept a horse and cart, and was well to do in the world. Witness knew a person of the name of Abraham Hewitt; he is sixty years of age.

William Lord, a blind man, was the next witness called, but his evidence was not important.

Peter Barnes saw the deceased at a colliery at Haltham-moor, on the Friday in question, November 27, at about half-past eight, and he seemed in good health.

Emma Bowers deposed that deceased passed the house with a load of coals about two o'clock on Friday, the 27th of November. Knew a man called Abraham Hewitt. Had seen him frequently at the house before the death of the deceased,—only once after. Never saw him there when deceased was at home.

Reginald Longshaw corroborated the former part of the preceding evidence.

Martha Livesey stated that she lived at Barton-bridge with her mother, who kept a shop. She sold arsenic. The shop is about one mile and a half from the house occupied by the deceased. Had known the prisoner for more than a year, from her coming to the shop, but did not know her by name. The prisoner came on Friday, November 27, between two and four o'clock in the afternoon. Thinks it was a little before three o'clock. She asked for threepenny worth of arsenic, which she said was for rats that infested the gutter. Witness asked if there were any children in the house? and prisoner said there were not. Prisoner put the arsenic in a basket and went away. On the 4th of January witness saw the prisoner at the house of Forrester, the officer. Forrester asked the prisoner if she knew witness? She said she had no recollection of her. Witness said that was strange, as prisoner had so often come to the shop. Prisoner said she had never been there. Witness said she had, and had come for arsenic. Prisoner replied she never had, and that the witness was mistaken.

In cross-examination the witness stated that the shop is one in which drugs are sold on one side, and drapery goods on the other. The customers are chiefly working people, and arsenic is frequently sold to them for rats. The cart of the deceased would pass the shop door on the way to Haltham-moor.

Sarah Hardman was present when the prisoner bought the arsenic from the last witness. The prisoner had on a blue plaid dress, a black velvet mantle, and a coarse white bonnet. She put the arsenic in a dark-coloured basket.

John Hardman, the brother of the last witness, corroborated her recollection as to the date.

Jane Bradshaw gave evidence of an unimportant character.

John Whitehead : Had known the deceased, and lodged in his house about six weeks before his death. Witness went away on the 24th of November and returned on the 28th. The prisoner told him on his return that her husband was very ill; had been taken ill on the Friday evening, and had vomited very much. He asked her if she had sent for a surgeon? and she said she had not, but had sent for some stuff to Mr. Hepworth's, the surgeon, who lives about 200 yards from the house of the deceased. Saw the deceased on the Sunday. He appeared very poorly, but did not complain of any particular pain. Mrs. Johnson carried away the vessel containing what he threw up. Saw him two or three times on the Monday, and he was much in the same state. Mrs. Mault, who lodged in the same house, had been absent, and she returned on the Tuesday evening. Saw the deceased on the Wednesday. He was then very ill. The prisoner asked witness to go up and read to him. Witness did so. He was then very sick, and the prisoner was attending him. Saw the deceased for the last time alive about four o'clock that day, when witness assisted in lifting him out of bed. He died at six o'clock that day. The prisoner and his wife appeared to live comfortably. Witness was not much at home.

In cross-examination the witness said it was the bible the prisoner asked him to read to her husband. She seemed to be attentive and kind to him.

Benjamin Millington, a cousin of the prisoner, and a local Wesleyan preacher, stated that on the 29th November he went to the house of the deceased, and found him in bed. He said he was not in pain, but was "inwardly done." He complained of sickness and thirst. Prisoner seemed quite cheerful, and not apprehending any danger. Witness went to preach in the neighbourhood. Returned in the evening, and found deceased much in the same state. Believed deceased and his wife had been in some way related before their marriage.

Margaret Bent stated that she was house-keeper to Mr. Rogerson, the landlord of the deceased. Went to the house of the deceased the evening he died. Found prisoner with Joseph Bethell in the stable. Prisoner came out and asked witness if she had heard of deceased being ill? saying he had been ill since Thursday. Witness said she had seen him come from the culprit that day. The prisoner then said, "Then it must have been Wednesday." Witness asked "What was to do with him?" She replied, "A bad cold and other things." She asked witness to go up stairs and see him. Said deceased would never come out of that bed alive. Witness said, "Eh, woman, how you talk!" The prisoner repeated the observation, saying his inside was quite done; that he had been ill for several months; they had not had a doctor, but were expecting one every minute. She said, "He'll never come down those stairs alive. I have quite prepared myself for it, though I have been laughing and talking with you; and I am going to Worsley to my father to get some hay, that the horse may have something to eat after he is dead."

Joseph Bethell, weaver: Saw deceased on the Saturday before his death. He was dressed and standing up. He was sick. About ten days after Johnson's death saw Hewitt at witness's door. He said something to witness's wife. He had once before seen Hewitt about deceased's house, but could not say at what time of day. It was about nine months before.

Mr. J. Hepworth, surgeon, at Croftshank, said he knew the deceased. Went to visit him on the 30th of November, about six o'clock in the evening. He complained of pain in the bowels, with vomiting and severe thirst. He said he had been relieved by some medicine sent him, a saline draught and some morphine pills, which had been sent on the Saturday. He (as witness understood) complained of having been taken ill after supper on Thursday evening. He complained of pain and heat in the throat. He said

his supper had been beefsteak and potatoes. He was not vomiting while witness was there, but witness saw some frothy mucus which had come from his stomach. Witness prescribed a preparation of carbonate of potash and spirit of nitre, and some James's powder with three quarters of a grain of calomel and some acetate of morphine. There would be about cent. per cent. of antimony in the James's powder. Saw him again on the Monday and on the Wednesday. He seemed better, but complained of a choking sensation in the throat. The vomiting had ceased. Continued the morphine and saline mixture, and mustard poultices and fomentations externally. On Thursday, the 4th of December, the day after the death, witness assisted at the *post-mortem* examination. The viscera were generally healthy. The interior surface of the stomach was highly injected, and the same appearances were presented throughout the alimentary canal, diminishing in intensity from the stomach downwards. The lips were excoriated; the gullet and bladder highly inflamed, and an unusually red or scarlet appearance of the lungs. These appearances might have arisen from any irritant cause. Never met with such as the result of natural causes. Arsenic would, in witness's opinion, produce such symptoms. Found a small quantity of something in the stomach witness thought was arsenic. It was not so big as a grain of sand. Could not undertake to say what it was. Might have been antimony. Was present when the body was disinterred. Marsh's test was applied by Mr. Lee in the presence of witness. There was a solution of magnesia sent by Mrs. Hepworth to Johnson's, as part of the medicine for him to take. Could not say if the matter tested was the thousandth part of a grain. It could not have caused death. In June, 1846, attended a young girl, the daughter of Abraham Hewitt, who was staying at the house of deceased. There was a solution of arsenic and a solution of magnesia in witness's shop. The former was of a red colour, the latter was white. There was no solution of arsenic missed from the shop, and it could not, in witness's absence, have been sent by mistake for the solution of magnesia.

Mr. John Lee, surgeon and lecturer on medical jurisprudence, stated that on the 4th of December he assisted with the last witness at the first *post-mortem* examination. Took a portion of the intestines and of the liver, and by Reinsch's test obtained slight film on the copper, but so slight that he could not say what it was. The body was exhumed again early in the present month, when the witness took a large portion of the internal parts, the stomach and the heart, and a portion of the thigh. These were examined the day after. A portion was first subjected to Marsh's test. There was a metallic deposit on a piece of cold porcelain. This was discharged by the action of chloride of lime. This would not discharge antimony, but whether it would discharge other metallic deposits besides arsenic was not certain. It would discharge arsenic. By another process a yellow precipitate was produced; and from these appearances and experiments he had formed the conclusion that there was arsenic in the body, which had been the cause of death.

Cross-examined : Was lecturer on medical jurisprudence at the Manchester Medical School. Could form no estimate of the quantity of the mineral in the metallic films. Knows of no other substance which would produce under the circumstances the same results. Much would depend on the purity of the tests.

Re-examined : The tests themselves had previously been tested.

Mr. Watson, analytical chemist, corroborated the preceding evidence.

Thomas Forrester, a police-officer, corroborated the statement of Miss Livesey as to the conversation between her and the prisoner at his house. When witness took prisoner into custody she said she did not know what arsenic was, and had never bought any in her life. Searched the house, but found no arsenic.

Mrs. Ann Hepworth deposed that on the 28th of November the prisoner came to Mr. Hepworth's surgery, saying that the deceased was ill, and had got, she thought, the English cholera. Witness gave her some fluid magnesia.

Cross-examined : The little girl Bethell came first, and the prisoner about ten minutes after.

Mrs. Maria Mault said the prisoner and his wife did not live happily together, and quarrelled a good deal. She spoke to several angry expressions of the prisoner on various occasions respecting her husband, saying she wished he was stiff—that she would make a deep burying of him, and would not ask one of his folks. The day he died, when told that Mr. Hepworth thought him better, she said he would never get better, and would die that night.

William Chapman deposed that deceased was formerly a tenant of Abraham Hewitt, who frequently came to his house, contrary to the wish of deceased. Once they had a fight.

Thomas Brooks, gardener at Sale-moor, deposed to seeing the prisoner meet Hewitt in a wood there, and had seen him kiss her.

Elizabeth Wood stated that she had seen the prisoner and Hewitt in bed together in Johnson's house at Sale-moor, and that she had told witness she liked him better than Johnson, and that if she could not have him without she would poison Johnson. The following Monday prisoner came to witness's father's house, and borrowed a shilling. She said she would go and see "if she could get without him without being found out."

Ellen Gatlley deposed to Hewitt's frequent visits to Johnson's house in his absence. Had seen him in Johnson's bedroom. Once saw Johnson strike him with a potato-fork on finding him in the kitchen. Prisoner had told witness that she liked Hewitt's little finger better than Johnson's whole body, and that she wished he never would come in alive.

The deposition of Robert Churchill, now deceased, was read, to show the intimacy of Hewitt with the prisoner, and the use of expressions respecting her husband similar to that already given.

James Shawcross and **William Longshaw** gave similar testimony.

Mr. Sergeant Wilkins addressed the jury for the defence.

His Lordship's summing up occupied about two hours.

The jury then retired, and, after some deliberation, returned a verdict of *Not Guilty*.

ANOTHER MURDER BY POISONING.

A coroner's inquiry, which has occupied several days, was concluded on Monday, the 28th ult., at the Pontypool Workhouse, Pontypool, respecting the death of John Thomas, aged ten days, the illegitimate child of Hannah Thomas, a pauper inmate of the union. The infant was born in the workhouse on the 16th of February. About a fortnight before that date the mother saw Mary Miller, another pauper, apply some sulphuric acid to a ringworm on her child's head. The pain made the child cry, which induced Thomas to ask Miller if she knew the nature of the lotion. Miller replied that the doctor told her it was strong poison, and she must be careful, for if it touched clothes it would make them rotten. The accused, on the 25th of February, when she had been only eight days confined, was seen in the kitchen with the baby in her arms. There, according to the workhouse regulation, she ought not to have been. On a shelf in this kitchen Miller kept the bottle containing the sulphuric acid, and also a teacup which she used when making use of the acid to wash her child's head. On the morning of the day on which the mother, as stated above, was seen in the kitchen, Miller left about two tablespoonfuls of the acid in the cup. She was seen with the cup in her hand by a woman of the name of Lewis. On the latter entering the kitchen she put the cup back on the shelf in a hurried manner, and her child was observed to be crying. Thomas then left,

and returned to the lying-in room. Shortly afterwards she complained to Margaret Thompson, a nurse, that her infant was ill. When she had left the kitchen, Miller perceived the cup was not in the same position she had left it on the shelf, and that the acid that had been in it was gone. Rees, a girl, saw the child on the lap of Thomas that day, and noticed that it vomited black froth, which she wiped off with a napkin. The prisoner said to Rees, "I wish to God my child was dead, as I could then go back to service." The infant died in bed the next morning, between five and six o'clock. No suspicions were entertained at the time that the child was poisoned until the morning of the 29th of February, when Miller and another woman were washing the prisoner's clothes, amongst which was some of the child's apparel, which they found in parts to be rotten. This aroused Miller's suspicions, who thought the rotten condition of the clothes much resembled the rotten state of her own child's dresses on which she had dropped some of the acid. On communicating her suspicions to the governor, the coroner of the district was apprised of the circumstances, when the exhumation of the body was determined on, and the facts already detailed were deposed to before the jury. Mr. Cossons, the surgeon of the union, stated that he attended the birth of the deceased, and it was a fine healthy child. He described at some length the *post-mortem* examination of the body and the analysis of the contents of the stomach. After a great mass of evidence had been taken the coroner summed up, and the jury, after a careful consultation, returned a verdict of "Wilful Murder" against Hannah Thomas, the mother of the deceased. On the following day she was removed to the county gaol, for trial at the ensuing assizes.

GOSSIP OF THE WEEK.

SUPPOSED MURDER.—(From the *Times* of April 3).—It may be remembered that an inquest was held, on the 2nd of November last, on the body of Rosetta Brown, twenty-one years of age, before Mr. Mills, deputy coroner for Middlesex, at which the evidence showed that she lived in the service of Mr. Jenkins, a surveyor, No. 22, Huntley-street, Tottenham-court-road. Mr. Jenkins stated that the deceased was to have been married on the day of her death to a young man named Payne, but that he (Mr. Jenkins), knowing that an affection existed between her and a lodger in his house, attended at the church and forbade the marriage. On the following day, whilst at dinner, his little child, five years old, came up stairs, and said Rosetta was lying in the coal-cellar, with a mask on. He ran down, and found the deceased lying on her back, with her head literally severed from her body, and a carving-knife lying near her. Mrs. Pope, sister to the deceased, and other relatives, wished to make a statement affecting an individual, whom they said they had no hesitation in declaring to be the murderer, but the deputy coroner refused to hear them, alleging, that if he allowed private character to be assailed, they might sit there till Doomsday. No medical man was examined, or *post-mortem* examination made. The jury, of which Mr. George Davey, of Tottenham-court-road, was foreman, expressed dissatisfaction at further evidence not being produced; but, after a long argument with the deputy coroner, returned a verdict:—"That the deceased committed the act herself, the state of her mind at the time not being known." The friends of the deceased, not being contented, had the body examined by Mr. Davidson, a surgeon, living in Marylebone, when it was ascertained that the girl had been seduced, and the surgeon gave it as his opinion that it was impossible she herself could have inflicted the wound which caused her death. The deceased had been threatened by the person suspected of seducing her, and Mrs. Pope had been warned by the partner of that person to get her away from Mr. Jenkins as soon as possible, and not suffer her to go out

after dark. Mrs. Pope had also been informed that the suspected person had become insane, and was in a lunatic asylum either at Norwich or Ipswich. Under these circumstances a letter was addressed to Mr. Wakley, the coroner, which, as he was out of town, fell into the hands of Mr. Mills, the deputy coroner, in reply to which the last-named gentleman stated that the verdict of the jury was unanimous, and that they had decided that, as jurymen, they would not be justified in making further inquiry into her private history. Mr. Pope then applied to Lord Wriothley Russell, the result of which was, that two months after the death of the young woman a statement appeared in one of the morning papers, and Mr. Francis Godbold, of Francis-street, Tottenham-court-road, one of the jury, wrote a letter to the editor contradicting the statement of Mr. Mills, as to the jury having been satisfied with the proceedings on the inquest, and hoping that a more searching investigation would be instituted. On the 22nd of last month Mrs. Pope obtained an interview with Mr. Wakley, and placed in his hands a written statement of all the particulars which had come to her knowledge. At the conclusion of the interview Mr. Wakley, who expressed a strong opinion on the subject, said she should hear from him, and accordingly, on Wednesday last, Mrs. Pope received a letter from Mr. Churchill, appointing a second interview between her and Mr. Wakley of the evening of that day. She attended, when Mr. Wakley endeavoured to dissuade her from having the body exhumed, on the ground that, if it should turn out after all that the deceased had herself committed the act, it would be a great exposure for the family. Mrs. Pope, however, persisted in demanding further investigation, and Mr. Wakley expressed his willingness to attend to any further proof that might be adduced, but has not as yet determined on the exhumation of the body. Thus this mysterious business rests at present, but it is understood that, in the event of the coroner refusing to have the body exhumed immediately, application will be made to Lord Denman, as Chief Coroner for England, and to Sir G. Grey, as Secretary of State, to exert their authority.—[Mr. Mills has written to the *Times*, insisting that the whole of this statement is false, and affirming that assertions of the same kind have been made the subject of a legal action against the *Morning Chronicle*. Our readers will, of course, believe the deputy magistrate in preference to the unknown reporter. In the meantime we shall be glad to hear Mr. Davidson's statement, as well as that of the medical gentleman called in to the case, and whom, Mr. Mills, no doubt, took care to examine. Ed.]

Our readers are doubtless aware that the Council of the National Institute have arranged to hold a *conversations* on Tuesday, the 13th instant, at which there can be little doubt there will be an abundant gathering of all those members of the profession interested in the welfare and objects of that body. This is the first time that the general practitioners, as a class, have ever been called together in this social manner, animated by the same hopes, leagued for the same ends, and working out, by their own unaided exertions, the uses and advantages that sometimes are, but too generally are not, conferred by acts of Parliament and royal charters. We hail this promise as an omen of better things, and we doubt not that the reunion will be both beneficial and attractive.

MODERN MEDICINE. How to CURE CONSTIPATION BY ONE DOSE!—Take of Scheele's prussic acid four drops, laudanum sixteen minims, compound spirits of ammonia two drachms, compound powder of nuxvomica two grains; fill up with bitter almond water, so that a six-ounce mixture may be made. Two tablespoonfuls are a dose, and a six-ounce mixture will do for six patients. N.B.—To secure efficiency, procure the bitter almond water of Mr. Jacob Bell!

WAR-OFFICE, March 23.—16th Foot: Assistant-Surgeon Benjamin Usher Hamilton, M.D., to be Surgeon, vice Thomas Young, who

retires upon half-pay; Henry Fowle Smith, gentleman, to be Assistant-Surgeon, vice Hamilton.—48th Foot: Christopher Wright Wray, gentleman, to be Assistant-Surgeon, vice Langley, promoted on the Staff.—65th Foot: Staff-Surgeon of the Second Class Samuel Currie, M.D., to be Surgeon, vice Martin, deceased.—71st Foot: Michael Allen Jane, gentleman, to be Assistant-Surgeon, vice Reade, appointed to the Staff.—97th Foot: Assistant-Surgeon Frederick Foaker, from the Staff, to be Surgeon, vice Irwin, deceased.—2nd West India Regiment: William Leggo Reid, M.D., to be Assistant-Surgeon, vice Macartney, appointed to the Staff.—Hospital Staff: Assistant-Surgeon William Leslie Langley, M.D., from the 46th Foot, to be Staff-Surgeon of the Second Class, vice Currie, appointed to the 65th Foot; Assistant-Surgeon Henry Cooper Reade, from 71st Foot, to be Assistant-Surgeon to the Forces, vice Foaker, promoted in 97th Foot; Assistant-Surgeon Christopher Macartney, M.B., from 2nd West India Regiment, to be Assistant-Surgeon to the Forces, vice Robertson, deceased.

APOTHECARIES' HALL.—Gentlemen admitted members April 1:—George Burton Payne, Henry Nevins, Thomas Balle Forster, John Lane Cutcliffe, George Augustus Martelbury Hepworth, James Surzewell, John Ingman, George Heiring, Wm. Nowell, and John Jessup Sewell.

MORALITY OF MEDICAL MEN.—From a return of prisoners given in the *Parisian Moniteur*, a fact very satisfactory to our profession has been made public, viz., that of all the professions the medical is the most moral. From 1828 to 1838 there were in France, 41,679 male prisoners, aged above twenty-five, under criminal charges. Of these there were 33 priests, 33 avocats, 9 avoués, 75 notaries, 66 huissiers, and not one medical man!

Mons. Combes has been elected a member of the Academy of Sciences.

The Municipal Council of Paris have decided that a new street shall bear the name of Ambrose Paré.

The influenza has been common in Munich, and with unusual severity.

MORTALITY TABLE.

For the Week ending Saturday, April 3, 1847.

Causes of Death.	Total.	Average of 5 Winters.
ALL CAUSES.....	1004	914
SPECIFIED CAUSES.....	1001	900
Zymotic (or Epidemic) Endemic, and Contagious Diseases.....	107	166

MORALITY TABLE 166

COURSE OF LECTURES ON CLINICAL MEDICINE,

Delivered in the THEATRE OF QUEEN'S COLLEGE, Birmingham.

By SAMUEL WRIGHT, M.D.,

Physician to Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham. Physician to the General Dispensary, Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

Special treatment of the typhoid fever of 1846 details of a case in illustration, and comments upon it, inferences concerning the treatment of this form of fever, difference in cases requiring different treatment illustrations and comments, depression the most common leading feature in typhoid fever, indications of it especially shown in the action of the heart & pulsations, value of persisting in a definite and well indicated plan of treatment, ammonia as a stimulant, observations upon cases in which it would seem to be contraindicated, case illustrating the value of wine and ammonia, another case in which neither was used.

GENTIANS.—In my last lecture I detailed to you the general features and treatment of the typhoid fever of 1846 reserving the more special particulars of it for the present occasion. One or two cases will be sufficient to convey to you the information I am now desirous of giving.

Susannah Griffiths, a spinster, aged twenty-three, was admitted into Queen's Hospital, under my care, on the 15th of October, last year. She was placed, you will remember, in the top front ward. She was not sufficiently conscious at the time of her arrival, nor indeed for some time afterwards, to give me any account of her commencing illness, but I learned from her sister, that the poor girl had been ill for three weeks prior to my seeing her, that she had kept her bed for a fortnight, and had had no medical assistance whatever.

When we first met at her bedside we found her in a low typhoid and semi-comatose condition. Her surface was cold and pale, except her hands, the fingers of which, up to their metacarpal articulations, were of a deep dusky red. She was quite unconscious of passing objects, and could only be roused, for a few seconds at a time, by shouting in her ear. We thus learned that she had some pain in her head, with a sense of heaviness; that she felt thirsty, but had no appetite. Her eyes were lustreless, and covered with films, pupils dilated, and scarcely sensible to light, respiration slow, irregular, and slightly embarrassed, pulse 164, small and feeble, impulse of the heart scarcely perceptible, and its systolic sound weaker than corresponded with the pulse at the wrist. Tongue dusky red at the edges and tip, and covered with a brown fur in the middle, it was quite dry, and its papilla elevated, gums swollen and vascular; teeth partially covered with sordes. The stroke sound of the chest was

everywhere clear, but the respiratory sound was occasionally, and in places, distinguished by a mucous rattle. The abdomen was tumid and somewhat tympanitic, and the epigastrium a little tender on pressure. Her breath was of a fensive, and the surface of her body exhaled a disagreeable musty sort of odour. She passed but little urine, which was deeper in colour than natural, smelt very strong, exhibited an alkaline reaction, but did not afford any evidence of containing free ammonia. Her bowels were costive.

She was ordered toast-water for drink, and, as she refused solid food, old bread soaked in milk, or in buttermilk, was directed to be given to her every four or five hours. The following medicines were prescribed—Cup stat, chlorid, 3ss; et rep post hora tertius, et alvus non respond.

R. Inf gentian, aque pure, aa ziv. sp ammon aromat, 3ij, tinct. hyoscyami, ʒij. Misce but must cupus cupat cochineia amplia duo tertii quaque hora cum pilul.

R. Hydragry chloridi, gr iij, pulv Jacobi veri, gr. ss; lytr. conia, q s ut fit pil. vj.

I ordered a mild dose of castor oil as an aperient, because in these cases you are never safe with active cathartics. Given in a moderate form these often do more than you expect from them, and so either increase the prostration (the reverse of your requirement in typhoid fever), or cause such irritation in the mucous membrane of the bowels as shows itself by frequent tenesmus, diarrhoea, or twisting pain, any one of which will, directly or indirectly, multiply the chances against you in treating such cases as these. The object is, gently to unload the bowels of any undue accumulation, but, at the same time, to do this without increasing the debility immediately by excessive intestinal discharge, or more slowly by continued irritation. It was to answer this intention that I prescribed castor oil—one of the mildest aperients we have, in small quantity, and advised its repetition, if necessary. In any cases in which you have to fear the consequences of lowering action, or of gastro-intestinal excitement, it is much better to proceed with a cautious repetition of aperients given limitedly, than to hazard a larger dose given at once. You can thus better feel your way, and push your treatment without the risk of compromising your patient's strength or safety. The case under consideration well illustrates the truth of what I say. Half an ounce of castor oil was a very moderate dose to give, and, if required, it might have

been repeated at a proper interval without fear. Fortunately, the first dose sufficed; we may anticipate what would have been the effect of giving double the quantity, or of giving any aperient of a more irritating nature. As I told you, at the time of first prescribing for this patient, I thought the generality of the symptoms were consequences of nervous depression. I thought the nervous system wanted rousing and sustaining, but, of course, gradually and guardedly. It was with this object that I prescribed the ammonia in the mixture. The cold skin, the quick, weak pulse, and, above all, the diminished impulse and sound of the heart, spoke of nervous depression. The dilated pupil and lustreless eye, and heavy pain in the head, with slight stupor, and the absence of all symptoms of active disturbance in the brain, told plainly that congestion of a passive kind was there. The very nature of the case forbade even local bleeding, and suggested, further, that the opposite treatment was necessary. Local blistering might, or might not, have done good—it would have been no easy matter to have raised a blister, by ordinary means, with such a state of skin; and had one risen, it would likely have constituted a trivial some slough—one of the worst of troubles in such cases. Then, as I have said, we trusted to the diffusible stimulant, ammonia, to dissipate the local congestions and balance the circulation, by imparting fresh energy to the nervous system. I gave the hyoscyamus in the mixture, to allay the gastric irritation; it was not severe, but it might have become worse had it not been prescribed for. Further, the patient, though seldom fully awake, did not sleep thoroughly, and I thought the hyoscyamus might procure her some slumber. This is of great advantage in the watchfulness of fever—a night's rest is often invaluable in these cases—and when hyoscyamus answers the purpose, it does so without occasioning the cerebral oppression so common after opium. I made the vehicle, equal parts of water and infusion of gentian—we must have had a vehicle of some kind, and perhaps water alone would have sufficed; but I chose to have equal parts of this and a bitter infusion, because of the value of the latter when there is a tendency to putrescence. As you are aware bitters are in some measure antiseptics, and I have often been made satisfied of their efficacy in typhoid cases, when the stomach has had power to retain them. I ordered the calomel in small doses, for there was a little more tension

in the region of the liver, and a greater extent of dulness on percussion, than there ought to be; there was also some sallowness of skin, and these things, added to a torpid state of bowels, led me to expect a sluggish condition of the biliary apparatus—a state of passive congestion, in fact, similar to what had been manifested in the brain. This proved to be the case, for, after the first few doses of the mercurial, an abundance of bile was discharged by the bowels, and most of the symptoms indicative of its retention, and of liver congestion, immediately disappeared. I administered the antimonial along with the jalomel, because I have learned from experience that it often corrects the latter in its action—makes it more certain and safe; and because I wanted its relaxing influence upon the skin, which, in this case, was dry and harsh and unyielding. So much for the treatment we commenced with.

On the 16th we found that the bowels had been freely unloaded by the castor oil, which had operated four times; the dejections were dark and offensive, and accompanied with much flatulency; less tympany to-day. Patient slept several hours last night. Tongue slightly improved, but more sordes on the teeth. Pupils less dilated, but the left eye completely covered with film. Surface quite cold; pulse 150, weak and trembling. The fingers quite free from congestion, but the cheeks marked by a circumscribed dusky-red blush. (This migratory congestion—at one time in the fingers, and at another in the cheeks—was a peculiar feature in this case during many days.) Pain in the head a little easier. Has taken her food tolerably well. Remedies to be continued. To have three ounces of wine, daily, at three doses.

17th. Bitter to-day. Expression of face better. No films on either eye—pupils wider, but more sensible to light. Tongue cleaner, and articulation more distinct. Pulse 140, but feeble; impulse of heart, and systolic sound, more appreciable. Head cool; bowels open; no pain anywhere.

The mixture and wine to be continued: the pills omitted. This change was made in the treatment, because the several indications expected to be met by the mercurial and antimonial medicines had been satisfactorily fulfilled, and there was no necessity for pushing these further.

18th. Tongue cleaner and more moist. Head hot; pulse 140, and very feeble; slept indifferently last night, during the greater part of which she hooted and shouted vociferously; thirst more urgent; bowels well open.

The hair to be cut close, and wet cloths applied to the head. The wine to be continued, and also the mixture, excepting that, in place of the water and bitter infusion, camphor mixture is to be the vehicle. This change was made in anticipation of any febrile reaction.

19th. In much the same state as yesterday. Pulse 140, feeble. Pupil more contracted; head cooler; face pale; return of congestion to the fingers; shouted frequently during the night; bowels well open; urine scanty and slightly ammoniacal. The mixture to be continued, and the wine diluted with its equal of beef-tea or sago. From this time to the 24th she continued almost stationary. She was then ordered three grains each of camphor and hyoscyamus, at bedtime: the other remedies to be continued.

The narcotics had the effect of soothing her irritability, and obtaining for her some refreshing sleep. There were the next morning more symptoms of improvement than we had previously seen.

On the 27th these favourable indications were still more manifest. In particular, they were shown in the altered expression of face, which was becoming, as I remarked to you at the time, more physiological. The tongue was also cleaner, and more moist; there were fewer sordes on the teeth; and neither the breath nor the perspiration had the offensive odour that at first marked this; bowels open; urine more abundant, and neutral; less shouting; appetite a little better. Remedies to be continued.

On the 29th she was still progressing favourably, except that the impulse of her heart, and its systolic sound, were still very weak. I therefore increased her wine to four glasses daily, and gave her an extra quantity of ammonia in her mixture.

From this date she improved as satisfactorily as could be desired: the treatment was continued for twelve days further, when, in addition to full diet, she was ordered the following:—

R. Inf. gentiane c. 3viij.; sodæ bicarb., ʒj.; sp. æth. nit., ʒij. M. ft. mist. jus cap. coch. ampla duo ter die. Cap. pil. rhôl. c. gr. v. pro re nata. These were administered merely to correct a little weakness and irregularity in the gastric and intestinal functions, and to increase the action of the kidneys; all of which intentions were in due time fulfilled, and the only remaining trouble was an absence of the catamenia. As I before told you, this was a not unfrequent sequela of the fever of last year. In this case, the patient was ordered tincture of sesquichloride of iron in infusion of quassia, and an occasional aloetic purge. The menstrual discharge shortly made its appearance, and the girl left the hospital well.

My note-book would enable me to furnish you with many examples of typhoid fever, treated similarly to the above, and with like results, during the summer and autumn of 1846. It is not requisite, however, for me to put various cases before you, when one will serve as a type of the whole, as regards their radical treatment. In the outline of the case given above, you have an index to the fever I refer to, as well as to its management, at least in so far as concerns my own practice. The general features of the ailment were sometimes varied with local pathological manifestations of one kind or other, but these were never such as to change the intrinsic character of the fever, or to render the stimulating and sustaining treatment objectionable or unnecessary.

You must understand, gentlemen, that I am not lecturing upon typhoid fever in general, but upon typhoid fever in particular—upon that variety of it which prevailed amongst us last year. Whilst, therefore, I speak with some degree of positiveness concerning its remedial management, I do not wish you to infer that the rules I have laid down will apply to whatever cases of typhoid or typhus fever may hereafter occur to you in practice. Were I to say thus much, I should only be delivering to you the language and sentiments of empiricism. In physic we have no rules that are not liable to exceptions, and it is as much a knowledge of the ones as of the other that constitutes a scientific and safe practitioner. If you were to go upon the undeviating plan of treating every case of typhoid fever with wine and ammonia, you would be guilty of the same indiscretion and prejudice with the man who would make the lancet and mercury his only remedies. Whatever inclination you may have for general rules of practice, always let it yield to the suggestions of particular cases. In doing this you will sometimes meet with an epidemic fever of the typhoid type which, contrary to that prevalent here a few months ago, exhibits many varieties, according to the age, temperament, and state of health of the individuals seized with it: this, of course, will call for as various a form of treatment. In a series of cases there may be local inflammatory tendencies—the brain, lungs, or gastro-intestinal mucous membrane, being the suffering organ. Here you would require local or general depletion, proportioned to the severity of the attack and the strength of the patient. In another series the organs above-mentioned, or the liver, or the kidneys, may be simply congested, and then corresponding counter-irritant and derivative measures would be needed. In a third series, the leading pathological condition may be one of nervous depression—all other morbid manifestations being secondary to it. Here, of course, your object would be to sustain and strengthen.

You may have all these varieties, nay more,

during one visitation of epidemic typhoid fever; or the cases may be altogether of one class, as happened in the fever of last year. My own experience and reflection upon this subject incline me to the belief that a state of vital depression is by far the most frequent radical morbid feature in the fever I speak of. This you recognise, as in the case I have quoted, by the expressed or exhibited feelings of languor; the laxity of the muscular tissues; the shrunken, anxious features; the sleeplessness, incoherence, and involuntary twitching of the limbs; the quick, weak, irregular pulse; and, above all, by the diminished impulse and systolic sound of the heart. These latter are indications that will rarely if ever fail you—make them your constant inquiry in treating fever!

Having satisfied yourselves of the pathological condition which chiefly requires to be met, meet it determinedly, and with perseverance. Never let the minor features of a case divert you from your proper purpose. If stimulation be indicated, none other measures can be; therefore, do not be betrayed into the exhibition of them, from the suggestions of symptoms merely. *A priori*, it might be urged that wine and ammonia are contraindicated by a hot dry mouth, flushed cheeks, injected conjunctiva, restlessness, thirst, and depraved secretions. But it must be remembered that the cause of all these things, in the cases I speak of, is vital depression. Remedy this, and the symptoms of it improve, as a matter of course. You have seen, in my practice of last year, how a persevering use of due stimulation in typhoid fever will lessen the frequency, and at the same time increase the force, of the pulse; dissipate the flush from the cheeks; moisten the mouth, and clean the tongue; dispose to sleep, and, by giving tone and energy to the system, improve those secretions that had become depraved from weakness. Even the suggestions of organic chemistry, valuable as they often are in the practical business of the bedside, are sometimes to be disregarded in the necessity that may exist for prosecuting any single and well-indicated plan of treatment. It might be argued, that when the urine is ammoniacal, the perspiration alkaline and foul like the breath, and there is a general tendency to putrescence, ammonia would be an unsuitable remedy. Yet you have several times seen all these morbid conditions corrected by this very medicinal. I have no doubt that any other diffusible stimulant which, like ammonia, has often a prolonged action, and little affects the sensorial functions, would have answered as well; but I know of none that in all these particulars is equal to ammonia, and therefore give it the preference.

One of the best cases illustrative of the value of stimulant treatment which I saw during the prevalence of the typhoid fever of 1846, was in the person of a little boy, aged eleven years, whom I attended in consultation with Mr. Francis Elkington of this town. He had been ill some days when I first saw him, and presented all the ordinary features of the fever. Mr. Elkington was treating him with bark, ammonia, and nitric ether, which seemed to me to be so judicious a plan as to deserve a continuance. On the following day the boy was in much the same state as before, and we agreed to give his medicine a little more frequently, and also to allow him more wine. In spite of this, his vital powers continued to fail, and on the occasion of our next visit, the subsequent day, the nurse told us it was not necessary to go up stairs, as the little fellow was "all but dead." Of course we visited him, notwithstanding the suggestion, but to all appearances it seemed as though we had come rather on ceremony than for service. For several hours he had lain in the condition in which we found him, and the nurse had declined administering either wine or medicine, from his inability to swallow. He was cold all over; pupils dilated, and quite insensible; eyes open and covered with films; action of heart inappreciable over its site; pulse not sufficiently distinguishable at the wrist to

A COURSE

OF

LECTURES ON SURGERY;

BY

SAMUEL COOPER, Esq., F.R.S.

Professor of Surgery to University College, London.
Consulting Surgeon to London University Hospital, &c.

GENTLEMEN,—Surgery is essentially a part of the healing art; it forms one of the divisions of medicine; and it becomes us, therefore, in commencing a course of lectures on this department of science, to ascertain in what it properly consists, and its limitations. Among the several departments of the healing art, surgery occupies a prominent position; so that we shall not greatly err if we divide the whole province of this art into two great branches, *Physic* and *Surgery*. Midwifery, another division of this extensive field, may, in so far as its manual operations are concerned, be considered as a subdivision of surgery, while the remainder is, properly speaking, a branch of the practice of medicine. The operations of the oculist and dentist are especially surgical.

The term surgery, if considered in its strict etymological sense, signifies the cure of diseases, the removal of the results of injuries and deformities by manual operations. Although this definition may be to a certain extent correct, as regards the art of surgery, it is by no means co-extensive with the science. We must not content ourselves with defining surgery as the mechanical part of medicine, nor draw the line of distinction between *physic* and *surgery* so strictly as to prohibit the surgeon from prescribing internal remedies in conjunction with external means. Such a procedure would in the present age be grossly absurd. As the surgeon cannot then be prevented from treating disease as well by internal remedies as external applications and manipulations, the line of demarcation between *physic* and *surgery* is less easily settled. We must look upon surgery as a science founded on the same principles as medicine, and acting, to a certain extent, by the same means for the alleviation of suffering. This science must be based, like medicine, on a right comprehension of the structure and functions of the human body, on a careful investigation of the causes of aberrations either of structure or function in the animal machine, and on an equally diligent study of the physiological and therapeutic action of remedial agents.

Even our mechanical operations are founded on applications of scientific principles. Take, as an example, the passing a ligature round an artery. The act of tying the artery is purely mechanical; but the principles on which the steps of the operation, and the intention of the surgeon in performing it, depend on a large number of scientific details which render the whole operation much more than a mechanical performance. In tying an artery for aneurism, it is necessary that a precise knowledge of the position and relations of the artery be well understood; and this is taught us by the preliminary study of anatomy. Pathology teaches us that aneurism, which is a tumour formed by the dilatation or rupture of an artery communicating with the vessel, and filled with blood from it, increases in size in consequence of the forcible propulsion of blood into it; while physiology informs us that the office of an artery is the conveyance of blood from the heart to every extremity of the body, and thus that the blood flows through the vessel in a certain direction. Anatomy and physiology further demonstrate that, if the main artery of a limb be obstructed, there are other channels through which the blood can flow, and thus furnish to the extremity the blood which is requisite for the fulfilment of its functions and the sustentation of its vitality. From a knowledge of these facts, the surgeon infers that, if the flow of blood into the aneurism be diminished or prevented, coagulation of the blood in the aneurism

say what kind of pulse it was; breathing hardly perceptible. There was no consciousness whatever of passing events, and nothing that we could say or do roused the poor creature: to sum his case up in few words, he had every appearance of being close upon the point of death. Still, he was *not dead*; and, acting upon the belief that "whilst there is life there is hope" (in such cases as these a very advisable belief), we determined not to lose even the last chance, and therefore proceeded to give him wine. The first teaspoonful put into his mouth remained some seconds there, and then passed with a feeble gurgle down his throat. We followed that dose by a similar one, and then another, and another, until half a glassful had been swallowed. We then let him rest for about a minute, at the end of which time his pulse had become perceptible at the wrist. This was the only sign of reaction, and, trifling though it was, it was encouraging, inasmuch as it showed us that there was vitality enough left to respond to stimulation. We therefore ordered that he should have a large wineglass (holding about an ounce and a half) of port given to him every other hour, and in the intervening hour a similar glass of strong beef-tea, containing two drachms of compound spirit of ammonia. One hour, you observe, he had the wine, and the next hour the beef-tea and ammonia. The remedies were strong for so young a subject, but the case was desperate, and we did not choose to abandon him whilst there was even a "forlorn hope" left.

We visited our patient the next morning, about fourteen hours having elapsed, and we found him on the night-chair, sufficiently comfortable and conscious to greet us with a smile. On Mr. Elkington asking him how he was, he answered in a strong voice, that he was better, and had just taken some coffee and bread and butter. In this short space of time his tongue had become moist, and had nearly lost its dark brown colour; the *sordes* had completely disappeared from his teeth; in fact, without enumerating the items in proof, I may say he had become a living intelligent creature! From this period there was only one uninterrupted and rapid progress to recovery. This case is one of the most remarkable of the kind I ever met with. I have no comments to offer upon it, for I think none are necessary; but I am happy in being able to refer you, for its corroboration, to the accomplished practitioner whose name I have quoted in connection with it.

I have told you that the only case in which I did not prescribe stimulants, in the typhoid fever of last year, the patient died. I will give you the particulars in a few words. The patient was a man named Thorp, living in William-street, who had been several days under the care of Mr. Carter of the General Dispensary, before I saw him. My attendance was requested, because of a sudden increase of general febrile symptoms. I found him with a pulse of 126 *per minute*, full, and somewhat hard; head hot, and slightly painful; face flushed; eyes rather glaring, but not intolerant of light; throat sore, and the membrane of the fauces reddened; thirst urgent; urine scanty and high-coloured; bowels confined.

The leading features were those of inflammatory fever, simply; but it was a question what turn the present state of things would take. The brain might be beginning to suffer, or scarlet fever might be impending. Under ordinary circumstances, depletion might have been recommended; but, knowing the vital depression of the general fever cases, I did not advise it. As a purgative, I ordered six grains of scammony, and three of calomel, to be taken at once. The mixture—which consisted of the following:—

R. Sodæ bicarb., potassæ nitratis, tinct. hyoscy., aa. ʒij.; sp. æth. nit., ʒij.; aquæ, ʒviij., M. ft. mist. cujus cap. coch. ampla duo tertiis horis—was to be continued.

In six hours after the administration of the purgative, I called upon the patient, and found that his bowels had been freely moved three

times: his general symptoms, however, were little altered. I ordered the following:—

R. Hydrag. chloridi, gr. iij.; pulv. Jacobi veri, gr. xii.; ext. conii, q.s. ut ft. pil. viij. Cap. i. singulis dosibus misturæ.

On the following day he was somewhat better; pulse 120, full, but softer than before; skin more moist; thirst less urgent; kidneys secreting properly; bowels open. Still there was considerable restlessness; the head was painful occasionally; there was slight inclination to wandering and perverseness; pupils more contracted than natural, and eyes glaring. The mixture and pills to be continued.

During the next two days the improvement was very marked; every untoward symptom had subsided, and only simple fever, in a very mild form, seemed to be left. The bowels were well open: the pills were omitted, and the mixture continued. To have beef-tea twice a day.

On the following day no symptoms were present, excepting those of general debility. The bowels were comfortably open, and nothing seemed to be required, except the recruiting of the patient's strength. He was ordered beef-tea three times a day, additionally to a little sago, arrowroot, &c., and this mixture:—

R. Quinæ disulphatis, gr. viij.; acidi sulph. dil., ʒj.; tre. cinchonæ c. ʒss.; mist. camph., ʒviijss.; misc. ft. mist. cujus cap. coch. ampla duo ter die.

For two days subsequently, he improved slightly in appetite and strength, and had partaken of a little mutton chop without any return of feverishness. His bowels were well opened twice or thrice daily.

But on this, the third day since the suspension of his mercury, his gums became swollen and painful, breath fetid, and jaw difficult of movement. He was ordered a continuance of his medicine and nutritive diet; wine occasionally, and his feet to be put in hot salt and water at bedtime.

The following day the salivation was very strong; and the parotid and sub-maxillary glands were largely swollen. Additionally to the other treatment, a mild gargism of chloride of soda was prescribed for his mouth. In spite, however, of all we could do, medicinally and by aliment, the man continued to sink, and died on the fourth day succeeding that on which the salivation appeared.

Considering the urgency of this case at its commencement, I think we could have hardly used milder remedial means consistently with anything like good judgment. Yet, mild as these measures were, the man sunk from them. Even in the face of his strong quick pulse, and threatened determination to the brain, I feared depletion, knowing the depressing tendency of the prevailing fever; yet these conditions required to be met by some means—could we have used safer? The quantity of mercury taken was trifling; and during, and subsequently to, its administration, the bowels were freely open. Directly that its services could be dispensed with, it was discontinued. Three days elapsed before salivation appeared, and yet the man sunk! And this, in spite of treatment calculated to sustain him. What would have been the consequence had we bled him well at first? It is probable he would not have rallied from the effects of it. Would it have been better to have given him ammonia during any period of the fever? I doubt it.

WAR-OFFICE, April 9.—25th Foot: Assistant-Surgeon Jonas King Carr, M.D., from the 63rd Foot, to be Assistant-Surgeon, vice Swift, who exchanges.—63rd Foot: Assistant-Surgeon Benjamin Swift, M.D., from the 25th Foot, to be Assistant-Surgeon, vice Carr, who exchanges.—Hospital Staff: John Clay Purves, M.D., to be Assistant-Surgeon to the Forces, vice Galland, who retires upon half-pay.

NAVAL APPOINTMENTS.—Assistant-Surgeons: J. B. H. Collings, of the *Hibernia*, to the *Trident*; Charles Roberts, of the *Vindictive*, to the *Nautilus*,

and obliteration and consequent cure, will follow. Such an example will show that both judgment and cure are requisite in the performance of operations, and that these, to be successful, must be based on scientific principles, drawn from anatomy, physiology, and pathology.

The question whether an operation is either requisite or proper for the cure of a surgical disease necessarily involves a large amount of scientific knowledge and practical experience, calling into action the highest functions of the mind. Reverting to the question with which I set out—the connection of physic and surgery—I may broadly state that they cannot be disjointed, since the principles of both are the same. Custom has introduced a distinction: some diseases being allotted to the physician, others to the surgeon, while a third set of cases form a debatable ground, occupied alternately by the one or the other, and where both meet. This division of duties is a purely artificial one, which, although convenient to a certain extent in practice and teaching, cannot be extended to the science. Notwithstanding these artificial distinctions, the treatment of disease in all its varied forms must be based on a sound knowledge of the anatomy, physiology, and pathology of the human body; and sad indeed must be the condition of the medical practitioner who starts on his career without a sufficient acquaintance with these all-important subjects.

You will perceive, gentlemen, from what I have already said, that anatomy and physiology must constitute the principal foundation of a well-conducted surgical education. Anatomy may be denominated the science of organization: it makes us acquainted with the qualities, situations, forms, connections, and textures of the organs of the human body. It not only investigates these forms and qualities, such as they are shown to us by the naked eye, but, with the assistance of microscope, it makes known to us the minute structure of each of the separate parts and tissues which enter into the formation of the organs themselves. Physiology contemplates these organs, when in action under the influence of vitality; revealing to us their functions, and exhibiting all the vital phenomena which are capable of being discovered by the curious observation of man. Hence, anatomy and physiology are the two sciences on which our knowledge of the structure and functions of our organs rests, while in a healthy and natural state; and hence the necessity of studying these sciences before we venture on the more complicated and difficult ground of pathology. What possible advantage can be gained by the student in the wards of our hospitals who is ignorant of these two primary sciences? He who is ignorant of the healthy structure and function of an organ cannot be supposed to be in a proper position to understand the abnormal changes to which such an organ is liable. He who knows nothing of the functions of an organ will be equally unable to appreciate functional disorder.

Anatomy and physiology conduct us to pathology—a word which, in its most general significance, implies the science of the changes to which the whole, or a part of the body, is subjected under the influences of causes which disturb its normal condition. To this science belong the investigation of the alterations in the texture, consistence, forms, relations, connections, and functions of organ. Morbid anatomy—an important branch of pathology—should be sedulously cultivated by the student, on account of the light it throws on the nature, seat, and cause of disease. While anatomy investigates the normal structure of organs, morbid anatomy examines the changes in structure induced by disease. It is not, however, coextensive with pathology, because the latter includes the investigation of diseases of function as well as of structure.

The scientific practitioner of physic or surgery will go still further: he will not only endeavour to cure disease when actually existing, but he will strive to prevent its occurrence. The art of preserving health, or hygiene, is not underserving of our special attention. Hygiene implies the

power of estimating the effects of all surrounding influences, on the organization and functions of the human body. This science directs us to the most available means of preserving every function free from disorder, and every organ from disease. It is of considerable importance in the practice of your profession, since you may be asked by your patients how a particular disease may be best avoided; and it will be most satisfactory to all parties if you are unable to solve the question propounded to you under such circumstances.

As you will have in the course of your practical duties to attend not only to the local ailments of your patients, but also to their constitutional state, and as you will be required to correct morbid conditions of the body, it is absolutely essential that you should be well acquainted with the nature and properties of the agents you will have to employ. Therapeutics, or the study of the nature and properties of remedial agents, is therefore of the highest importance. In addition to the study of the peculiar effects of medicines, their sources, properties, and doses, we find a most important auxiliary to all treatment of disease in the consideration of diet and regimen.

Several other sciences more or less intimately connected with surgery form integral parts of a sound surgical education. Comparative anatomy, chemistry, botany, and natural history, throw a flood of light on medical science. They cannot therefore, be totally neglected without detriment to the student.

In addition to this mass of knowledge, and without which a man cannot be a good practical surgeon, experience must be placed as of the most vital importance. An intimate knowledge of the names and symptoms and treatment of disease derived from books will not constitute either a good physician or surgeon. He must possess, in addition to this knowledge obtained from the writings of his celebrated predecessors, the capability of recognising disease and unravelling the symptoms of the more obscure cases, when presented for examination, so as to arrive, when possible, at the real nature of the affection he is about to treat. Again, he must know not only what is written of remedies in books, but what is their real effect when administered to the patient; and this kind of knowledge can only be gained by oft-repeated examination and treatment of actual cases. This constitutes experience. By experience I do not mean to say that a surgeon should have seen an immense number of cases; but that he should have attentively observed them, and have drawn careful and mature deductions from the phenomena he has witnessed in the course of his practice. The theoretical or book practitioner may be capable of descending most fluently on the nature, symptoms, and phenomena of disease; but place a patient before him and you immediately detect the quality of his information: he is unable to apply his knowledge and recognise the disease with which he may be well acquainted theoretically.

I have thus demonstrated to you, gentlemen, the necessity of experience, and I shall now proceed to explain how true experience is to be gained. True experience, I have told you, does not depend so much on the number of the cases you observe as the manner in which you observe them. It is only by an attentive study of particular cases, guided and enlightened by the general principles you obtain in the lecture-room, and assisted by the remarks made by the surgeon or physician under whose care the patient is placed, that you will arrive at a true knowledge of disease. With those aids you will be enabled to obtain that *lucus eruditus*, without which you will cut a sorry figure in your future professional life. No condition can be more deplorable than that of a high-minded and honourable man who should rashly undertake the responsible duties of a medical practitioner unprepared by a sufficient course of study. Doubt and difficulty will attend every step he takes, and he will be harassed by the consciousness of his

inability for the duties he has undertaken, and the danger in which he is constantly placing the lives and limbs of his fellow-creatures. This deplorable picture of the state of mind in which every honourable man must be placed who neglects to obtain a competent knowledge of his profession will, I hope, serve as an inducement to ardent and sustained study while you have still the ample opportunities before you which are furnished by the noble school in which you are now placed.

And now for the mode in which experience should be gained. In the course of lectures I have now commenced I shall place before you the principles and practice of surgery; but this will prove insufficient for the education of a surgeon unless accompanied by careful attendance on the practice of the hospital. It is there that you will gain the *lucus eruditus*; there that you will see what I am about aiming to describe. You will have both medical and surgical cases in the hospital attached to this institution in sufficient numbers to enable you to observe the chief phases of disease. Even these will more than suffice for your careful study, for it is infinitely better for you to observe well a few cases than to pay an insufficient attention to a large number. By confining your attention in this manner to a few cases at a time, you will gain the habit of careful examination; you will imprint the symptoms of disease more vividly and durably on your mind, so as to be able to recognise them at once when called to examine a case. Another and most useful adjunct to experience consists in preserving careful and methodical written records of cases. By so doing, you not only imprint the symptoms more forcibly on your mind at the time, but you preserve the materials which are capable of reviving your recollection in after years. You must bear in mind, however, that art is long and life short; that your education must not be confined to the three or four short years you will pass in the schools; but that every day of your professional life ought to afford you additional knowledge and experience.

The surgeon, in addition to the qualifications I have already described, requires certain others which are not so requisite in the practice of medicine. He often inflicts the most atrocious pain for beneficial purposes. He therefore requires a steady hand, good sight, and firmness of mind, not to be shaken by sudden or unforeseen difficulties, nor by the cries and suffering of the patient. Here, want of coolness and composure would prove highly injurious to his patient. Dexterity is another important qualification of the surgeon. This may be acquired by practice; but coolness, firmness, or courage, are gifts of nature. Unless you acquire dexterity in performing the surgical manipulations you will naturally lose the confidence of your patients; the clumsy application of so simple a matter as a bandage will be instantly detected, and you will lose caste in the estimation of your patients. It is therefore of importance that you should take every opportunity of practising the minor manipulations of surgery, and for this purpose you should anxiously aspire to the office of dresser to one of the surgeons of our hospital, which here is given in accordance with the merits of the candidates.

Much of your success, gentlemen, in future life will depend on kindness and propriety of manner towards your patients; they are usually incapable of ascertaining the amount of your professional knowledge, but they readily detect a want of kindly feeling and interest for their ultimate welfare. They will cease to place confidence in one who appears wanting in this quality. As your future life will be devoted to the relief of human suffering, you cannot but sympathise with the misfortunes of your patients; and this sympathy ought in every case to beget kindness of feeling and manner. Especially should you show this feeling to your poorer patients, who, in addition to the pain and misery of disease, bear the oppressive burden of poverty. Among the ancients no such division of prac-

ties into medicine and surgery existed as that of the present day. The writings of Hippocrates, Galen, Celsus, and Albucasis, comprise both these subjects. They did not recognise the modern artificial division of medical science. They were then essentially general practitioners, who at present have the care of by far the greater proportion of cases.

It was not until the clergy became the physicians of the middle ages that the two departments were severed. The Council of Tours, in prohibiting the clergy from shedding blood, effected this division. Surgery was then abandoned to the laity, who, in those days of barbarism, were plunged in the direst ignorance. Operations were performed by a set of menials, under the immediate direction and control of the priest-physician; and thus those who, by the use of the razor, were accustomed to employ sharp instruments, became surgeons.

Has this division conduced to the advancement of medical science? Is a question of considerable interest; to which it would be difficult to give a satisfactory answer. That division of labour conduces to the perfection of particular departments is an undoubted fact—provided each sets out with the preliminary information which is requisite for both. There can be no reasonable doubt that the students of medicine and surgery should receive the same preliminary education—that they should go through the same course of elementary studies—since both the sciences are built on the same foundation.

I cannot agree with those who would annihilate the regular physician and surgeon. Our lives are not sufficiently prolonged, and our powers of mind sufficiently strong, to embrace the whole wide field of medical science, so as to attain to perfection in each department. The pure physician should understand the general principles of surgery, although he may neglect the details; while the pure surgeon should be conversant with the principles and, to a certain extent, the details of medicine, so as to enable him to treat such general symptoms as may arise during the progress of surgical diseases.

ORIGINAL CONTRIBUTIONS.

ACCOUNT OF THE CHOLERA WHICH PREVAILED IN THE 86th REGIMENT, STATIONED AT KURRACHEE DURING APRIL AND MAY, 1846.

By A. THOM, Esq., Surgeon, 86th Regiment.

The disease appeared first in the 86th Regiment, and I believe we had a hundred cases in hospital before it had decided set in with the other corps; the first cases were almost universally fatal, the virulence of the disease having been most concentrated at its first appearance, and becoming gradually less uncontrollable and less general as its progress continued. Thus of the first 100 admissions, 79 died, 21 recovered; of the second 100 admissions, 66 died, 34 recovered; of the third 100 admissions, 50 died, 50 recovered; of the fourth 100 admissions, 40 died, 60 recovered.

On the 14th, 15th, and 16th, particularly the two first of these days, the cases were generally brought in in a state of collapse, and death followed in three or four hours.

But the peculiarity in many cases was, that there was neither vomiting nor purging, or only one of them, and in by no means a profuse quantity. Another circumstance which struck me in some of the first cases was, that before even the natural hue of the skin had been replaced by that livid look so characteristic of the disease, the pulse was almost imperceptible at the wrists, the eyes turned up, and the voice hollow and feeble; in an hour after, such cases would be in *articulo mortis*. But in these cases cramp of the lower extremities was severe, although seldom extending to the abdomen.

The first class of cases were those where the

attack was equally sudden, and the collapse preceded the vomiting and purging of serous fluid, or appeared simultaneously with these symptoms; and when cramps of the legs and thighs, arms and abdominal muscles, were most violent and intolerable.

Again, we had a third class, where the patient was suddenly attacked with vomiting and purging of congealed stools, cramp of legs, arms, and belly, rapidly inducing prostration of strength and early collapse often within an hour or two of the first attack.

Lastly, there was a number of cases in which there were evident signs of reaction, or an attempt of nature to bring about this, but in many instances the brief effort was too much for the system, and it rapidly sunk; but, in general, this class was more manageable than the others, and not unfrequently terminated in fever; and we were very glad to have a bad case of fever instead of a doubtful one of cholera.

The four types of the disease to which I have just alluded occurred in the order of succession in which I have placed them, each predominating in the four groups of cases which I have ranged to show the gradual modification of the disease by time.

In three-fourths of the cases the attacks were sudden, often within a few minutes; in the other there were occasional precursory signs for a few hours, or even a day beforehand. The first indications were a sudden sense of malaise, sinking, and prostration of strength, with restlessness and jactitation, accompanied by vertigo, deafness, loss of vision in some, alteration or hollowness of voice, and weak and slow respiration, nausea, and vomiting, purging of serous fluid, with intense thirst and sensation of burning heat at the precordium or course of the colon. The circulation seemed as if suddenly impeded, especially in the extreme vessels and capillaries, and collapse quickly followed; the features became shrunk, and the lip and skin assumed a ghastly and livid hue, which often pervaded the whole body; the pulse weak or imperceptible at the wrist, and the skin rapidly became cold and clammy, and covered with copious perspiration. Now, with regard to the spasmodic symptoms, they were generally most remarkable in the first stages, and commonly assailed the muscles of the inferior extremities, but very often extended to the arms, head, and abdomen—in fact, the whole body. The biliary and renal secretions seemed to have ceased, and, indeed, this may be said to have been the case with every other secretion, excepting those of the skin and mucous membrane of the stomach and intestines, and, in women nursing, of the secretion of milk.

Now, although these symptoms were those generally met with, they were not universal, and it was rare to find them all in one individual. The purely pathognomonic symptoms of the disease, as we met it, were loss of nervous power; weakened circulation, tending to more or less degree of collapse; and profuse cold perspiration, to such an extent that the clothes and bed of the patient seemed wringing wet. This last in addition to precordial distress were never-failing symptoms present in every case, and remained till the action of the heart ceased altogether. There was often an absence of purging, vomiting, and cramp, the three next most prominent symptoms; but in no case do I, or any one else, recollect that the skin did not pour out fluid in large quantities: this might have been called the chief symptom.

The mind was usually clear and collected, unless disturbed by the excruciating sufferings arising from severe and protracted spasms of the whole body; and, in a very few cases, I have seen it wander as coma, which usually closed the scene, set in.

Treatment.—As there is no pretension to success in any part of our practice, I will just advert to the different plans adopted to arrest the disease or alleviate the sufferings of the hapless creatures who passed under our care. I vainly fancied that it was not difficult to treat this disease with ordinary effect, judging from experience of Asiatic

cholera, in its visit to England, and was quite prepared in my mind with an array of remedies to oppose this pestilence on its native ground; but it seemed to bid defiance to every mode of cure which I or others adopted.

From the want of medical officers it was impossible to pay minute attention to individual cases; but the numbers came in so rapidly that we could, under almost similar circumstances, give precisely the same remedies to a given number, and the rapidity of the malady showed in a few hours the success attending them: thus enabling us to draw a fair conclusion from the considerable number of data. As failure followed, another plan was tried with the next series of cases admitted, and so on, till, feeling at a loss what next to do, we had to revert to treatment which we had condemned before. Thus it turned out that exactly the same plans of treatment were employed in each of the 400 cases which were successively admitted, and with the results as exhibited. That sixty cases out of the last hundred were cured we might have had some reason to assume, had not the same practice been so unfortunate in the first hundred. It is true many men appeared to improve after our treatment in the last hundred cases which came into hospital; but our past disappointments led us to assume little merit in this apparent success, even in the cases that recovered.

Conceiving the disease to be of a highly congestive nature, suddenly occurring in full, powerful, robust men, V.S. was a natural remedy to be adopted, and its high reputation by some gave us some encouragement to pursue this practice for awhile; but what availed it to open a vein in a man in collapse, as every case was at the first outbreak. A few drops of dark blood issued, and the patient steadily sunk. Now, in cases which had sudden collapse, and no vomiting and purging to debilitate the system, we ought to have had some success with this practice; but it was not so. But, after the disease had in some degree exhausted its violence, we found bleeding apparently useful in many cases; but if reaction followed venesection, it was just as likely that the stimulus of mercury would have been followed by a similar result.

Mercury was one of the earliest and most general medicines in use; it was given in large and repeated doses of ten or twenty grains of calomel or blue pill, with one or two grains of opium united, particularly in cases where there was much vomiting and gastric irritation. This treatment was almost invariably attended by relief, and quieted the vomiting and spasms; but still the system would not rally, reaction did not follow, and the profuse perspiration of the skin and collapse went on to the usual termination. In the modified cases, and those which took place after the 17th and 18th, this practice was generally resorted to after having tried others, being found quite as certain as any other.

Croton oil, in doses of two drops, with one or two grains of opium, was given with much temporary advantage in bad cases, and apparently contributed to the recovery of others. It certainly seems an invaluable remedy, and in many cases of vomiting, purging, and spasms, the disease was arrested at the outset; still, in the earlier cases, it had no influence over the circulation, and nothing seemed capable of arousing the nervous and circulating system to action even after the profuse vomiting and purging were arrested; and I confess we could accomplish this last object so often that we were frequently led to indulge hope, which, alas! proved vain.

The acetate of lead, in doses of one, two, or three grains, and one-eighth of a grain of acet. of morphia, was employed to stop those profuse watery dejections which continued in some cases after reaction had taken place; and in this point of view it was a most useful remedy. Of course in those cases where vomiting and purging are the first symptoms, and collapse appears to be their consequence, the only use of this remedy was resorted to, and with very good encouragement.

The use of tartar emetic and hydrocyanic acid was not found to afford sufficient evidence of being preferable or even equal to the other remedies mentioned, to have had an extensive trial, or reverted to a second time.

But the use of hydrocyanic acid by itself in water was of equal benefit in allaying the gastric irritation; and in that distressing state of the stomach marked by retching and rejection of almost everything taken into it, which exists for some days after the more imminent danger is past, I think a more efficient remedy cannot well be found.

Saline remedies and diluents were used according to the state and inclination of the patient's stomach. An incessant craving for drink, for the sake of the coolness which it produced, was a most common and the most distressing, because never yielding, symptom. Cold water was sought for by many, and after two or three draughts, being rejected, it would lie on the stomach. Others would only use soda-water or lemonade; and the character of the blood showed that, if the last could be introduced into the system, it would be of much use in correcting the changes therein existing. Nitrous acid, much diluted with cold water, was occasionally accepted by the patient, and quieted the vomiting and allayed the pressing calls for drink.

The stimuli which were used consisted in brandy diluted with water, or wine, ammonia, ether, assafoetida, the various essential oils, &c. But I do not know any mode by which we were more successful in rousing the system after the profuse discharges had been stopped than by enemata of sago mixed with brandy or wine, and a few drops of T. opii conjoined. By this treatment, especially the brandy injection, repeated every hour or so, I have seen men rally in a most wonderful way; and, unless the pulse had wholly ceased at the wrist, it was always more affected by stimuli exhibited in this way than any other. I would strongly recommend it as an auxiliary in certain cases of cholera.

Friction of turpentine, mustard and vinegar, &c., were resorted to in all cases; hot water to produce vesication, and hot applications in every form and shape, were used as external remedies.

After the first danger was past, a free use of wine, beer, nutritious diet, and tonic medicines was required; and I never saw so many cases in so low a state recover, without running more generally into fever. It is quite astonishing how much wine and beer could be used without affecting the brain or head."

ROYAL BERKSHIRE HOSPITAL.

SURGICAL REPORTS AND OBSERVATIONS.

By F. A. BULLEY, Esq., F.R.C.S., Surgeon to the Hospital.

FRACTURE OF THE SPINE.—DEATH.—POST-MORTEM APPEARANCES.

John P., aged thirty-six, admitted September 17, 1846, on account of a fracture of one of the dorsal vertebra, which he had received while assisting in removing the wooden centres of a railway bridge. In lowering a large beam of timber by a rope working in a block, one end of it had swung round, and, striking him suddenly on the back, felled him to the ground. His companions, finding that he had lost all power over his lower limbs, and as he complained of intense pain in the back and loins, conveyed him without delay to the hospital.

On examination, the spine was found to be fractured in the situation of the fifth or sixth dorsal vertebra, a large soft swelling, from blood effused in considerable quantity underneath the integument over the seat of fracture, preventing the exact nature of the injury being at first clearly ascertained; but from the continuous linear regularity of the spinous processes of the bones, above and below the fracture, there appeared to be no considerable displacement, either

backwards or forwards, of the separated portions of the column; he suffered excruciating pain in the part, as well as in the abdomen, extending on the left side towards the back in the direction of the kidney. The sensibility and voluntary muscular power of the lower limbs were entirely lost. He had vomited immediately after the accident, and continued to do so for some time after admission into the hospital. Thirty leeches were ordered to be applied over the seat of fracture, to be followed by a bran poultice, made with a strong decoction of poppy-heads and chamomile flowers to the part. To have an opiate draught at night.

18th. Has been very sick at intervals during the night. The urine, owing to the paralysed condition of the bladder, has been drawn off by the catheter both last night and this morning, unmixed with blood, and without any particular ammoniacal smell. Has had no relief from his bowels since the accident. The pain in the back and abdomen continues; the swelling over the seat of fracture is subsiding so as to allow of a more particular examination of the part, by which it is clearly evident, from an unusual mobility of the fifth dorsal bone, that this vertebra has been fractured. To repeat the opiate draught at night.

19th. The sickness has, in a great measure, subsided. Had a good deal of pain in the situation of the fracture last night, but is easier this morning. The bladder is distended with urine, which, when drawn off by the catheter, is of a straw colour, slightly albuminous and alkaline, but without any particular smell. Feels his appetite failing, so that he has no desire for solid food. To have broth and other nutritious liquids in small quantities and often. The anodyne draught to be repeated.

21st. No change in his symptoms during yesterday; last night the pain in the back was greater than usual, and lasted longer; he is, however, free from any uneasiness this morning, as has been the case generally in the morning since his admission; but the pain in the left kidney has been persistent of its being greater than he has before felt it. Natural appetite decreasing; he has an anxious and distressed look; tongue red at the tip and edges, and he complains of excessive feverish thirst. The lower extremities, which were at first above the average temperature of the body, are now quite cold. Habere olei ricini 3vj. at bedtime.

23rd. The bowels have been freely moved by the oil. The pain in the back and left kidney has continued unrelieved. On passing the catheter this morning, a considerable quantity of blood was observed for the first time dissolved in the urine, followed shortly afterwards by an oozing of sanious muco-purulent fluid from the urethra. Complains particularly of pain on pressure over the bladder. Extremities still cold, insensible, and motionless. The natural sensibility of the surface of the abdomen remains unaltered as far down as Poupart's ligament, where it is suddenly lost. To be removed to a water-bed, and his legs to be swathed in cotton-wool, and bandaged in flannel. To repeat the opiate at night.

27th. Has continued much in the same state as last report. Has suffered a good deal of pain in the back, especially during the night, as well as in the kidneys, and in different parts of the abdomen. The pain in the bladder has increased, and is more constant; urine still bloody, and has a very offensive ammoniacal smell.

30th. Urine still bloody and offensive, and every attempt to pass the catheter into the bladder in the gentlest manner is followed by a stream of fluid blood. Has been constantly suffering from fever, apparently hectic, since last report, with night sweats and other symptoms of great constitutional disturbance. There is a hard, doughy feel above the pubis, as if from the bladder being full of coagulated blood. The respiration, which had up to this time been in some degree assisted by the natural movements of the thorax, is now entirely diaphragmatic and abdominal. Slight electro-galvanic shocks have been

directed down the legs, which have had the effect of raising the temperature of the limbs, and creating a feeling of warmth to the touch, which the wadding and flannel did not seem capable of producing. He is also conscious himself of a sensation of warmth passing down the legs.

Oct. 2nd. The respiration, which was yesterday entirely diaphragmatic, has to-day become partially thoracic. The emaciation of his body has progressively increased. The night sweats and hectic fever have continued unabated; the feeling of hardness on pressure over the bladder, even when completely emptied by the catheter, is unaltered.

It would be tedious to note the minute indications of the patient's progressive decline; sufficient to state that, from this date, he gradually became weaker and weaker, the urine diminishing in quantity, but mixed with a larger quantity of pus and blood, and indeed, for a few days before he died, scarcely anything but bloody pus seemed to pass through the catheter; a bed-sore, which had a few days previously appeared upon the right buttock, had, notwithstanding every care, increased in size and depth, forming an irregular sloughy hollow; and an artery which traversed the bottom of the wound gave way the night before he died, occasioning a hemorrhage to the extent of about a pint, which, when discovered, was easily arrested by pressure. This comparatively little bleeding, however, seemed too much for his enfeebled system to bear, for from this time he quickly sunk, and died in the morning of October 6, ten days from the date of the accident, retaining his consciousness to the last.

Post-mortem Inspection Twelve Hours after Death.—On exposing the cavity of the abdomen the intestines generally had a pale, bloodless appearance, but there were no signs of any part of them, with the exception of a small portion of the ileum, having been affected by the accident. The liver, which had been uninjured, was natural in structure, participating only in the anemic condition of the other viscera. At the lower part of the abdomen, on the right side, the ileum, at a short distance from the valve, was found to be thickened apparently from previous inflammation, and agglutinated by a thick inelastic medium to the peritoneal investment of the bladder.

The parietes of the bladder were generally increased in density, so as to be in some parts considerably more than an inch in thickness, more especially on the fore part of the organ, where an abscess, as large as a walnut, had been formed in the hypertrophied tissue, the cavity of which was only separated from the interior of the bladder by a thin membranous partition, but had no communication with it; there was another, but a smaller one, on the right side, and this, as well as the larger one, was filled with half-purrid unhealthy-looking pus. The mucous lining of the bladder had entirely lost its natural appearance, being universally covered with flakes of yellow lymph, intermixed with flat adherent patches of coagulated blood from the rupture of vessels on different parts of its surface. On making pressure along the tract of the ureters, from above downwards, a considerable quantity of purulent urine escaped from their orifices into the bladder, more especially from the left as connected with the kidney, in which the patient had during life complained of the greatest amount of pain.

The pelvis of each kidney was more or less coated with flakes of coagulated lymph of the same kind as was observed in the bladder; but, except in one small spot, there was no appearance of ruptured surface, so that the quantity of blood in the urine, which had latterly been so great, could hardly be considered, except, perhaps, in a very small degree, to have had its origin in these organs. The left kidney was somewhat larger and more vascular than the right, and appeared to have been subject to a subacute inflammation of the same kind as had affected the bladder, but not to so great an extent.

On cutting through the integument covering the fractured vertebra, a thick layer of softish coagulated blood was observed underneath it, occupying a considerable space over the injured part, thickest in the centre, and gradually diminishing till at its circumference the clot was as thin as paper, and ultimately lost in the cellular tissue. In its central portion it extended downwards towards the spine, separating the muscles from each other, and the deeper ones partially from the bones; and the whole of them were in a softened and flabby state, from having been so long in contact with the effused and decomposing blood. The vertebral column at this part, both above and below the fracture, had the appearance of having been bathed in blood, from the extensive effusion caused by the rupture of one or two branches of the dorsal spinal veins, which seemed to have been the principal source of the external hemorrhage.

On removing the broken arch of the bone, and those of two or three of the contiguous sound ones, the theca vertebralis was for a considerable distance upwards and downwards separated from its attachment to the spinal canal by a thickish layer of coagulated blood, so considerable at one part as to diminish the capacity of the tube, and press upon and somewhat flatten the spinal cord. The cord itself did not appear to be pressed upon by any portion of the fractured arch of the bone, nor was there any considerable alteration in the direction of the medullary canal by the displacement of either the upper or the lower portion of the column; but the medullary matter was for some distance softer than usual, and of a rosy pink colour, the result, apparently, of the secondary inflammation to which it had been subject; the roots of the nerves arising from this altered portion were also in a softened state, and of the same colour as the substance of the cord.

The immediate injury to the bone consisted of a fracture of the base of the arch on each side, close to the body of the vertebra, attended, however, with very slight displacement; there appeared, also, to have been a fracture of the lower part of the body of the same bone, also without displacement, which had become partially united, for on endeavouring, with some slight force, to remove the spinal column from the body, the partial union gave way at this part, leaving a shell of bone a little more than one-eighth of an inch in thickness attached to the subjacent calilage.

Remarks.—The foregoing case may probably be considered as the record merely of the ordinary progress, and not uncommon result, of a spinal fracture; but, as it differed in several important pathological particulars from most of those which I have had an opportunity of observing, I shall be excused for giving it rather more in detail than I should otherwise have done. My attention was more particularly drawn to the altered condition of the urinary bladder by some able observations of Dr. Snow, lately published in the *Medical Times and Gazette*, tending to show that the morbid changes in this organ that occasionally followed fractures and injuries of the spine were influenced, if not produced, by a highly alkaline state of the urine (resulting from the decomposition of its urea and animal matter), which, being allowed to accumulate within it, was the means of setting up an irritation of its mucous lining, as evidenced by the increased mucous discharge, which he believed to be rather the consequence than the cause of the alkaline state of the urine, as was supposed by Mr. Curling and others; and that subsequently, the same cause continuing to operate, the whole of the structures of the organ became morbidly thickened and ultimately disorganized; and in some cases the decomposition was propagated in a retrograde manner along the ureters to the kidney, at last destroying the patient.

To prevent or moderate these ill effects, it is recommended that the bladder should be emptied more frequently than is commonly done, and that it should be syringed with warm water after each operation, to remove any small quantity of mucus or alkaline urine that remains, which, if

allowed to do so, would have a tendency to communicate the same alkaline irritating quality to any quantity of urine which might afterwards accumulate in the organ. What might have been the result in the present instance (where the morbid alteration was unusually great), if such means had been carefully pursued, I cannot take upon myself to say; but I should be disposed to adopt them in a similar case as a valuable pathological suggestion, worthy of more extended investigation.

I have omitted to mention that, shortly after the patient's admission, I applied some degree of extension to the spine; but whether this may have had any effect in rectifying any original displacement, I cannot exactly say, the precise degree of displacement being from the first obscured by the swelling; but, from what I could observe *post-mortem*, it may have done some little good; at any rate it seemed to have done no harm, as it put him to no additional pain, and certainly could not have increased the already complete paralysis; and, as I had heard and read of some instances where it had been employed with impunity, and even beneficially, I thought myself justified in cautiously adopting it. It was performed by fixing the body to the head of the bed, with steady and gentle traction to the lower limbs, by careful assistants.

The electro-magnetic currents which were passed down the lower extremities from the spine were observed on each occasion to cause the muscles to contract spasmodically, and raise the limbs from their supine and straight position on the bed; but, as these effects may be produced by similar means on dead animal matter, the circumstance is not remarkable; but it is worthy of observation that the usual vibratory sensations were felt no farther than Poupart's ligament, where they abruptly ceased; and the only benefit the patient received from these means was from the comfortable sensation of warmth in the limbs which they undoubtedly appeared to produce, and which must have tended, in some degree, to alleviate his sufferings.

MERCURY.—ITS INFLUENCE UPON THE SYSTEM, AND THE INDICATIONS FOR ITS EMPLOYMENT.

By CHARLES SEARLE, M.D., of Bath.

Mr. Smith, in the *Medical Times* of April 10, having submitted to your readers some very luminous observations on the operation of mercury, I beg leave to be permitted to support Mr. Smith's views, and add my own, which, as an Indian practitioner, may possess some claim to attention upon this interesting subject, by furnishing the following, extracted from my recent work on "The Philosophy of Life, Health, and Disease."

Of Calomel.—Whatever be the preparation of mercury administered, the condition in which it is received into the system from the stomach I believe to be that of a chloride, seeing that it must be first subjected to the influence of the hydrochloric acid of the stomach's secretion, and dissolved, before it can be received into the circulation. Hence it is, in my opinion, that calomel (the chloride of mercury) is so much more certain and determinate in its effects, and therefore so superior as a remedy to all and every other preparation of mercury we possess.

"The operation of all remedies received into the stomach, I believe to be in admixture with the blood, after their absorption from the stomach; experiments recently made having established this in my mind beyond question. The stomach, nevertheless, is subject, doubtless, as much as the skin, to irritation and other local agencies operating upon its surface; and thus, through its nervous sensibilities, also, may it be affected, as well as other organs connected with it; but neither calomel, jalap, rhubarb, wine, nor many of the numerous things administered as remedies, do so specifically affect it—not even ipecacuanha!

An infusion of this substance, injected into a vein of the leg, operates as an emetic in a quarter of the time required by any quantity administered by the stomach. These, then, when taken, are accordingly first absorbed into the blood, and each, during its circulation, severally operates in its own particular way—jalap as a purgative, and ipecacuanha as an emetic—either directly upon the organ influenced, or indirectly so, by first influencing the brain and nervous connections of the part. In proof of this, the same remedies applied to a blistered surface, from which they become severally absorbed, and in like manner operate as when taken into the stomach.

"Mercurials increase Capillary Excitement.—Calomel, when absorbed by the veins from the stomach and bowels, in its passage with the blood through the liver, to which it is immediately conveyed, excites this organ to increased secretory function; hence the bilious evacuation which so constantly succeeds to the use of a grain or more. Proceeding from the liver, and admitted into the general current of the circulation, its operation I believe to be specific on the capillary system at large, exciting these vessels to increased action. Hence its general influence as a stimulant to the whole system, its renowned deobstruent power, and its operation on the glandular system, in increasing all the secretions. Its operation in exciting the capillary arteries, and thereby secretion, necessarily removes obstruction from the exhalant vessels, and congestion from their venous terminations—the cause of exudation; and thus is exudation prevented, and absorption at the same time increased; and hence the accredited action of mercury upon the absorbents, in removing exudation of whatever kind, and the various dropsical affections. Its operation on the capillary system being general, the action of the heart and that of the brain, through the medium of their organic structure, is excited also, and, in short, all the functions. It thus operates probably by imparting qualities to the blood, by which its constituent particles may have a greater affinity for oxygen—the vitalizing principle; and thus may increased chemical action in the blood and its consequence—excitement—take place throughout the system. But whether this be the mode of its operation, or not, the effect is, as I have described it, excitement to the general system.

"Indications which Mercury fulfils.—The power of mercury in increasing capillary action is further evinced by the febrile commotion it excites in the system, and the buffed blood of those under its more abundant influence—effects succeeding to its exhibition which should be guardedly watched (generally occurring when it has ceased to operate as an evacuant), and when they arise its further use should, in a general way, be prohibited, though in some cases it may be employed with great advantage upon the principle (noticed when treating of blood-letting) of exalting the general excitement of the system, in relief of a local or partial affection: thus showing its use in inflammations of the bowels, and numerous other organic inflammations. But, speaking of its employment in a general way, it may be observed, that the indications for its use in inflammatory affections are limited to the atonic stage, and that of oppression. In no case should it be given in the intermediate or more active stage of inflammation, involving the heart's excitement, save in very guarded doses, and in conjunction with other evacuations. But when the more active condition of inflammation or of fever has been moderated by bleeding and other evacuations, or when debility has succeeded to previous excess of excitement, the atonic condition of these affections of the capillary system, its administration supports a due action of the capillaries, excites the secretions, and invigorates the heart's action, in common with the rest of the functions, and accordingly becomes our chief remedy; and in combination with opium, to moderate its excitement and allay irritation, carried to the extent of inducing increased salivary secretion,

which appears to mark its ultimate effect for good, is of a remedial character the most valuable.

"Calomel, its Effects with Reference to Quantity."

—Upon the subject of quantity I have a few observations to make of much importance. I have endeavoured to prove, in various parts of my work (which, although addressed to the public, is nevertheless, I trust, deserving the attention of the profession), that all agents, in their operation on the system, whatever those agents may be, whether physical or moral, or whether operating upon a part of the system, or upon the whole, have their effects determined, and in all cases bounded, by the quantity of influence imparted. Thus, wine, in moderate quantity, produces exhilaration and excitement; excess of it, atony and death. Heat in moderation produces excitement; excess of it, as in a severe burn or scald, mortification and death. The reverse of heat, cold, in like manner, within a certain range, as in the plunge of a cold bath, produces a glow and excitement, extreme cold, on the other hand, palsy and death. Anger in moderation produces vehemence and excitement; extreme anger, or rage, on the contrary, often deprives the person of utterance and propriety. Fear will induce a man to fly; fright, on the contrary, fixes him to the spot. In extreme grief no tears are shed, in moderate grief they flow abundantly. Enough has been said, I think, to establish the fact I have in view, and which, in reference to its application in a variety of ways, has been too much neglected, and especially so in the administration of mercury. A grain or two of calomel, my experience justifies me in saying, will in all cases (unless there exists some specific disease obstructing the blood in its passage to or through the liver), with very few exceptions, produce one or more bilious evacuations; this it does by moderately exciting the natural action of the liver, to which it becomes, when absorbed from the stomach, immediately applied. If the object, therefore, contemplated in the administration of this remedy be the increase of the biliary secretion, it should be given in a quantity limited to from one to three grains; whereas it is an every-day practice to give it in a large dose, to prevent, as practitioners say, its griping the patient. Now, griping, I maintain, is the natural effect of an acrid condition of, or long-retained bile, in the liver or its appendage, the gall-bladder; and, if this takes place when I administer a small dose, I hail it as the best evidence that the remedy was required, and in the extent of dose in which I have administered it; as I am thus dislodging the enemy, the cause, not infrequently, of all the patient's ailment; whereas a large dose—what does it do? It so hurries the circulation through the secretory apparatus, that secretion is not affected, the excess of excitement paralyzes the natural endowment of the part, and consequently there is either no secretion, or secretion of an altered kind, and perhaps without griping. This, in some cases of disease, may be a very proper measure, and I know it to be so; but not in fulfilment of the purpose mentioned, namely, that of increasing the ordinary biliary secretion.

Calomel, its Value as a Remedy.—The fruits of my experience justify me in declaring, that if there is any single remedy in the cure of disease meriting the name of universal, that remedy is calomel. The explanation I have given of its operation, and the universality of its influence on the system in exciting the functions of all the organs, and increasing all the secretions, render it evident, I conceive, that it fulfils indications of one kind or other in the treatment, with few exceptions, of every disease, which are all, it may be truly said, with very few exceptions indeed, based upon depression of the active energies, of life, health, as I have said before, consisting in the due action and efficient performance of the various functions of the system. Judiciously employed, I can say with confidence, in opposition to much prejudice on the subject, founded on the circumstances which first introduced it into practice in this country, and its too

commonly improper mode of administration (the principles by which its employment should be regulated not being understood), that calomel is as harmless as iron, or any other of the numerous articles of daily remedial administration. This conviction, be it remembered, is the fruit of thirty years' experience, twenty of which were spent in India, where this is the chief remedy employed in the cure of disease, and one of universal use both by native and European practitioners.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF MEDICINE.

Meeting of April 6; M. BLOIN in the Chair.

TYPHOID FEVER.

A report was read by M. Gaultien de Claubry on a communication of Dr. Ragaine, relative to an epidemic of typhoid fever at Saint Mand (Orne).

Dr. Ragaine insists upon the contagious nature of the disorder, and upon its treatment by the exhibition of saline purgatives after one or two emetics.

The reporter remarked that it was, to say the least, singular that, in Paris, typhoid fever was considered not to be contagious: this was the doctrine most generally adopted; and yet when physicians, having completed their studies, returned to the country for the purpose of practicing medicine, in a short time their opinion was altogether modified on the particular point. The conclusions of the report were favourable to the paper.

M. Rochoux thought it very singular that the same disorder was declared contagious in the country, and not so in Paris: this difference of opinion depended upon the fact that typhus and typhoid fever, two very distinct maladies, were always confounded. Their chief differences consisted in the presence of a constant eruption in typhus, and in the much shorter duration of this malady.

M. Piorry did not consider it was proper to establish symptomatic differences of this sort between two maladies so closely allied: the anatomical lesions accompanying each disorder were the real elements from which positive pathological distinctions might be deduced. The system of considering disease as an entity—abstractedly from the organic conditions—separately from the temporary and successive modifications in each viscera, produced exclusive and unitary therapeutic ideas, and led to the adoption of one line of treatment exclusively—venesection, purgatives, &c. This was the result, in the Parisian hospitals, of erroneous ideas on general pathology. As to statistics, the academy knew that they were brought forward in support of the most opposite doctrines: Professor Piorry was inclined to admit the contagious nature of typhoid fever, and thought that it might not be unfrequently observed in very severe cases.

Professor Bouilland endeavoured to establish the superiority of venesection over every other treatment in typhoid fever: he did not believe in contagion.

M. Louis observed that no doubt could exist as to the contagious nature of typhoid fever in the provinces; the numerous cases of M. Gondron, Bretonneau, and Putégnat, demonstrated the fact beyond the possibility of a doubt. In Paris M. Louis had also observed cases which proved the existence of contagion. On three occasions M. Louis had noticed in his wards the development of typhoid fever in consequence of the admission of a severe case of that malady. It was quite true that in hospitals this was rare, because the greater number of patients could be exposed with perfect impunity to contagion: some having already been affected with

typhoid fever, others having passed the age at which it is observed. M. Louis was of opinion that typhus differed materially from typhoid fever, and particularly by the absence of the alterations of Peyer's glands, so constant in the latter.—Meeting adjourned at five.

FACULTY OF MEDICINE.

[The following pages are an abstract of the first lectures, by which Professor Andral opened his course at the beginning of the winter: we forward them, first, in order that the sketch we have endeavoured to lay before the readers of the *Medical Times* may be as complete as possible; and secondly, because the subject which these lectures treat of is now, and appeared to us, interesting.]

LECTURES ON GENERAL PATHOLOGY, BY PROFESSOR ANDRAL.

The history of particular cases, that of each disease, still leaves the mind unsatisfied, and does not completely establish the science of pathology. The tendency to generalization inherent to human intelligence leads us to connect facts in their constant and general points of contact. It is the object of this course to deduce from individual cases, principles and laws—using at the same time a degree of reserve proportioned to, and destined to curb, the eagerness of imagination.

The elements of disease are to be sought for, in the first place, in the physical alterations of the body; and secondly, in the modifications of its dynamic powers. The former do not constitute disease, but occasion a certain disorder in the accomplishment of the functions.

Disease can exist independently of any physical change in our organs—we should say any appreciable change, for we are not warranted in stating that no change exists, merely because we cannot detect it, as it may, and frequently does, baffle investigation.

The study of physical alterations is still in its infancy. Simple morbid anatomy is insufficient; structural anatomy, as it is taught to us by the microscope, is also of very great assistance; but chemistry must likewise be called in to complete the researches of the anatomist and microscopist, and give them a definitive value.

From the correct knowledge of physical and dynamic changes, the laws which constitute the basis of pathology may be deduced. These alterations must be studied separately, and each in all its details; but the difficulty of analysis is considerably increased by the fact that they are generally combined so as to form groups which we unite, artificially, and call disease; and new discoveries daily throw disorder into these arbitrary classifications and render the institution of a permanent nomenclature a very arduous, if not an impossible, task.

Thus, in fever, the dynamic alterations of vital powers are always the same—heat, frequency of pulse, &c.; but its concomitant physical changes vary with each age, with each school, with each new discovery. At one time fever is considered isolately; at another it is connected with physical changes of our structures variable with each successive doctrine, let it be humorism, vitalism, or solidism. Thus, again, the word inflammation recalls to the mind a certain number of phenomena which are always the same, but to this day it is hard still to say what is the precise nature of the accompanying physical alteration.

Turning first to the physical alterations of our structures, we are at starting embarrassed to know if we should begin with their study in the organs, the tissues, or the liquids of the body. None of these parts are simple; we must, therefore decompose them, and seek in each of their constituent elements what part it takes in the production of disease. In these elements we find mediate and immediate principles. The former may be altered in quantity, quality, situation, and even in nature. The latter may also vary in these various respects, or be abnormally developed. From the mediate principles

emanate the immediate, and from these our solids and our fluids. We must consequently inquire into the changes of the blood, and the alterations of those fluids which are formed from the blood. In the changes of the solids we must consider the alterations of nutrition, and the various new productions which they sometimes present to our observation.

ALTERATION OF THE VITAL PRINCIPLES OF THE BODY

Cases are found in the system, some of them necessary to the continuance of health, others accidentally evolved. The former may be modified in their quality or situation, or be in a state of combination, incarceration, or freedom.

Combined gases are met with in all parts of the body thus, by the union of oxygen and nitrogen with other substances, most of our textures are constituted, but cases must be admitted to exist in which the natural proportions of these elements are modified. In the blood we find oxygen, hydrogen, and carbonic acid in a state of dissolution, may they not in some cases be liberated, and remain in the heart or vessels in their gaseous condition, or escape from the particles and surfaces of the body? These questions are not by any means futile, they are justified by the fact that free gases have been found in the circulating system, and that under nervous influence, as in hysteria for instance, gaseous productions have been known to escape from, or to accumulate over, certain surfaces of the body. From the skin from the surface of respiratory organs, they have been discharged and collected; they may vary in quantity and in nature, from the skin, for instance, nitrogen and carbonic acid are evolved. M. Colard de Martigny has shown that a high degree of temperature increases the quantity of carbonic acid thus liberated, he has also stated, adducing experimental proof, that an abundant animal diet increases the quantity of nitrogen, and diminishes the amount of carbonic acid gas discharged from the surface, and that a contrary result is the consequence of sparse and vegetable diet. Now, it is more than probable that a certain connection does exist between these differences of proportion of the evolved gases and certain morbid conditions of the system and, therefore, the prosecution of these physiological inquiries must prove eventually interesting to the progress of pathology. From the respiratory organs, carbonic acid and nitrogen also escape. The quantity of nitrogen discharged, as Mr. Milne Edwards has proved, is less considerable in cold than in warm weather, although in a cold atmosphere more nitrogen is absorbed. Thus in winter, either the blood will remain loaded with an excess of azote, or else, when separated from the blood, that gas will not pass out through the lungs, but be eliminated by other organs, some of our fluids will, therefore, in winter contain more nitrogen than they do in summer. The influence of the nature of the nutriment on the pulmonary exhalation of nitrogen has not been completely studied. With regard to disease, we find that M. Comdet, of Geneva, states that in diabetics, more azote and less carbonic acid are secreted from the lungs than during health.

We have stated that carbonic acid is also separated from the blood by the lungs. Its quantity varies according to the age, sex, and constitution of each individual from childhood upwards that quantity increases to the age of thirty. The quantity of carbon evolved from the lungs of a child of twelve years, during one hour, has been calculated to equal four or five grammes in weight, and increases up to fourteen grammes per hour, from fifty to fifty that amount remains stationary, and diminishes with age. In the male a greater quantity of carbonic acid is discharged from the lungs than in the female sex, during menstruation it has been positively ascertained that the evolution of the gas from the respiratory surface is arrested in a temporary manner. It is increased by subacute diet and fermented liquors, and diminished by abstinence, according to Spallanzani, Prout,

and Bousingault. During sleep it is also diminished. Nysten inquired into the influence of disease upon this interesting phenomenon, but his researches have remained incomplete. It appears, however, that in chronic maladies the lungs separate less carbonic acid than in acute disorders.

In the mucous cavities of the digestive organs gaseous air is also developed, and in general under the influence of purely chemical causes. In hysteria a variety of tympanitis has been observed, and it is not uninteresting to remark that the gaseous accumulation sometimes disappears spontaneously, no evacuation whatever having taken place to account for the fact. These intestinal gases are also formed in certain conditions of hæmorrhoids—in putrid and adynamic disorders.

In other mucous cavities gas may be secreted, but the occurrence is very rare, and is always the result of disease. In a dead but not decomposed body Lobstein found the gall-bladder distended with air. The urethra, uterus, and vagina have been said also to exude gaseous products, but the facts are not well proved.

Gas is never found naturally in serous membranes, but often during disease it is never secreted by the membrane itself but always arises from undecomposed or decomposed morbid products, from gangrene, or communication through an ulcerated part with atmospheric air, as in pneumothorax. Cases have been reported of gas in the arachnoid and ventricles, but they require further confirmation. In the pericardium, Liennec was disposed to admit the possibility of the secretion of air, but, if true, it must be exceedingly rare.

In the cellular tissue, air is almost always introduced by wounds, however, Senac, Levein, Portal, and P. Franckham, reported cases of spontaneous emphysema.

Gases have been found in the heart in vessels in three distinct instances—1, when the body was putrid, 2, sometimes after particular exertions, and 3, in some cases of death from hæmorrhage. Spontaneously an anæmic state it is true, in the cavities of the heart and due to a diminution of quantity of the blood, to a change in its nature, or to the excessive amount of gas contained in the circulating fluid. The presence of air in the circulating system is productive of various accidents. Morgagni notices a case of sudden apoplectic death due to the existence of gas in the cerebral vessels. Sudden oppression and distress followed the accidental introduction of air into the veins at the neck during operations performed upon that region.

Water is the only liquid mediate principle which need occupy our attention it forms the greatest part of all our solids or liquids. The changes of quantity of the water exercise an undoubted influence over the production of certain pathological facts. It may, for instance, diminish or increase in the blood and also in our various secretions. In the solids of the body we find that the amount of water undergoes a gradual decrease in childhood till age, and influences the texture and elasticity of our organs. In the water we find acids, alkalis, and salts, the proportions of which elements are modified by the continued changes in the amount of the water.

The solid mediate principles may be either simple or compound. The former are four in number—viz., carbon, phosphorus, sulphur, and iron.

The carbon is either in combination with oxygen or in its pure state. In childhood and advanced years, less carbon is consumed than in infancy, but in childhood it is employed for the growth of the body, in old age it is deposited in a pure state in the lungs, which renders more or less incapable of respiration, increasing thereby the dangers of pneumonia. In consumption these deposits sometimes take place, and have been observed to coincide with an anæmic state which has lasted for years (N. Guillot). If such deposits do not take place in old age, the carbon

must of all necessity remain in the blood, and there occasion more or less morbid change.

Phosphorus exists in the body either free or combined with oxygen, it is a constituting part of fibrine and albumen, it exists in the brain, where it varies with the age of the individual (Denis), and is said to diminish in some cases of insanity (Combe).

We know nothing of the varieties of quantity of the sulphur naturally contained in our tissues: it exists in fibrine and albumen, on the surface of and around certain ulcers, in some abscesses, and on the intestine, to which it communicates a slate colour, due to hydrosulphate of iron (Vogel).

Iron we find in the hair, in the blood, in the black pigmentum of the body. Many other simple bodies exist in our system, potassium and calcium, for instance, but they have not been studied.

The salts natural to the body may vary in quantity, state, or situation. With regard to quantity, we find, for instance, that an increase of the alkaline salts of the blood always corresponds with diminution of its fibrine, as in scurvy, diminution of these salts in the bones constitutes osteomalacia, and the perspiration of gouty subjects is, according to Berzélius, loaded with saline matter. As to their state, the salts may become solid, and form concretions, as in the urinary or gall bladder. The situation of these salts may also vary, we find them occasionally in the walls of arteries, or deposited on the valves of the heart, or on the surface of the lung (phosphatic lime).

In disease, new salts may be produced. Thus, sulphuret of ammonia has been said to exist in the blood, in the urine sometimes, oxalates, and in the solid parts uric acid and of lime are deposited in cases of gout.

The acidity or alkalinity of our fluids is a most important condition, thus, the diminution of the acidity of the gastric juice must impair digestion; its increase may influence unfavourably the health of the stomach.

Having glanced at the alterations of the mediate principles we now turn to the consideration of the immediate principles of the system. They should be studied during health and disease, in chyle, blood lymph secreted fluids, solid structures, and morbid products in all cases they may be considered as deriving their origin from one substance protein. Let us first examine those which contain nitrogen, we will afterwards enumerate those principles which do not contain that element.

Albumen is the first immediate principle which we have to investigate, its quantity may vary in the blood from age or disease. In all our secretions to be found in the fluids, separated from the blood by inflammation, it is more abundant than in those which are extravasated in consequence of some obstacle to the freedom of circulation. In the solids of the body, albumen varies with the age of the individual, in a child aged one day they contain 1 per cent., at eight years the solids contain 7 per cent., of albumen.

In the crystalline lens, Berzélius says that fluid albumen may be found, and M. Lassarri has attributed its opacity in cataract to the solidification of that albumen.

In tubercles a matter albumen is said to exist it can be occasionally detected in the urine in the serous contents of cysts and in pus, even after its filtration.

Fibrine is less abundant in the system than albumen, it is, in its solid state, the basis of muscular texture, and in a liquid condition can be met with in lymph, chyle and serum, in the blood, its quantity increases from the presence of inflammation, and diminishes in diseases of an opposite and debilitating character, as will be hereafter seen in the study of hæmorrhages. Extravasated fibrine coagulates in a short time, but its solidification may be prevented or delayed by the action of certain substances such as alkaline salts. Inflammation sometimes causes fibrine to escape from the blood, together with a certain amount of albumen, water, and salts, and it is

then deposited on the surface of the solids, in the shape of coagulable or plastic lymph, and occasionally in flakes floating in serum; or again, in granulations, of which instances may be often seen on the surface of mucous membranes. Fibrinary exudations not unfrequently become vascular, and are by some pathologists looked upon as the origin of numerous accidental products, such as cancer, tubercle, &c.—an opinion which, to say the least, must be looked upon as premature.

Cascia resembles closely albumen and fibrine; its presence has not only been detected in milk, but in some cases in blood, saliva, bile, urine, pus, and tubercular deposits: we must, however, pause before we consider its existence in the last-named substances as perfectly demonstrated.

Urea varies considerably in quantity in the urine, according to the nature of the diet of each subject, and also according to ages and sexes: thus Lecanu asserts that more urea is separated in a given time by the male than by the female adult, more by the female than by the child, and more by the child than by the aged of either sex. In disease, the proportion of urea contained in the renal secretion varies considerably. When abandoned to itself, urine is decomposed, and urea is converted into carbonate of ammonia—a substance of the same elementary composition, but differing from it in the arrangement of its component atoms. It is in the bladder, not in the kidneys, that this transformation is operated. Accidentally, urea may be found in the blood, as in granular kidney, in violent cholera, when the urinary secretion is entirely suppressed (Henle). Urea is not formed in the kidneys; as a proof of the assertion, we may quote Prévost and Dumas, who, having removed the kidneys of an animal, found urea in the blood. Henle also detected urea in the blood of a healthy ox. In albuminuria, urea has been found in the various serous effusions. Nycten mentions two instances in which urea was detected in substances thrown up from the stomach; but in one of the cases he acknowledges that an imposition was practised upon him by the patient.

Uric acid is a compound originating from urea, and its quantity may be increased in the urine without disease of the kidneys, as in gravel, intense fever, and cirrhosis; in the latter disorder, it constitutes, together with dropsy, an almost positive sign of the hepatic affection. In gout, not only is uric acid superabundant in the urine, but it is also found in a solid condition in the neighbourhood of the joints.

We are unacquainted with the alterations of the immediate principles of bile, with the exception of those of its colouring matter, which is sometimes found in the serum of blood and in the various secretions, in consequence of nervous disturbances of the liver, of inflammation of that viscus, of changes in its texture, or of mechanical impediments to the excretion of bile. In the present state of science we are unable to state if this colouring matter is absorbed after its formation in the chylific organs, or if it is created in a primary manner in the blood.

Gelatin is another immediate principle, the quantity of which may vary in the bones, in cartilaginous or tendinous structures, and may also be found accidentally in some morbid productions.

Ptyaline exists naturally in saliva, and the changes in its proportions may exercise some influence on the accomplishment of digestion.

Pepsin is an organic substance found in the gastric juice; its quantity and qualities are modified by various circumstances, and probably are influenced by the state of the nervous system; this would explain several disturbances of the digestive functions, hitherto unaccounted for, and amongst others those produced in some individuals by mental anxiety.

We now turn to the consideration of those immediate principles which do not contain azote.

Sugar of milk exists naturally in milk, but it has also been met with in other fluids. Schnerger detected its presence in the peritoneal effusion found in the body of a woman recently delivered,

and Henle in the intestines of women after arrest of the lacteal secretion. These assertions, however, require further confirmation.

Lactic acid is abundantly diffused in our system. It has the property of dissolving rapidly phosphate of lime, and Henle fancies that its presence in large quantities in the blood may sometimes coincide with mollities ossium. Mitscherlich states that lactic acid is formed in the capillaries, and there acts upon the alkaline carbonates in such a manner as to liberate carbonic acid, which returns with the venous blood to the lungs in order to be evolved. The hypothesis is plausible, but not absolutely demonstrated.

Fatty principles have been met with in chyle, blood, pus, and nervous textures. They sometimes pass from the solid to the liquid state, and also from the latter to the former condition. Thus, cholesterine, usually fluid in bile, is often the basis of solid concretions. Fatty principles may accidentally be detected in unexpected situations: thus, cholesterine exists occasionally in certain dropsical secretions, in the shape of minute bright particles; often in hydrocele, or in ovarian cysts. In some viscera we may also notice the preternatural development of fatty matter—in the liver, for instance. All the immediate principles which have hitherto occupied our attention may be produced during health; but others also must be examined which are formed only in disease. Thus oxalic acid, hippuric acid, and sugar, do not appear in the healthy urine. If, however, animals are fed on sweet vegetable substances, or on cane-sugar, uncrySTALLIZABLE sugar is found during digestion in the intestines. M. Bernard has shown that this sugar is absorbed into the blood, where it disappears; but, if certain diseases are present, this transformation of the sugar in the blood ceases to be performed—the saccharine matter is expelled with the urine and other secretions, and the animal invariably dies within a very short period. Saccharine matter is thereby proved to be indispensable to a proper and healthy assimilation and nutrition. We are perfectly ignorant of the chemical cause by which this elaboration is prevented in the blood of diabetic subjects. It is not, therefore, with disease of the kidney that we must connect the presence of sugar in the urine, but with a deep disturbance of the digestive functions, and of the vitality of the blood.

D. M'CARTHY, D.M.P.

Vienna.

As an anecdote, may be mentioned that a glazier's apprentice, engaged in the cleaning of windows, fell from a fourth story (in Vienna very high), and got up quite unhurt.

Professor Rokitsensky, whom the Vienna journals call the founder of pathological medicine (?), is laid up with typhus.—The great botanist, M. Endlicher, has been especially deputed by the Emperor to arrange and install the University of Cracow—the first in the empire to be worked on the newly improved educational system of Austria.

ON THE CONSECUTIVE PHENOMENA AND SYMPTOMS OF OTHER OPERATIONS.—An important question relating to this new discovery is, whether the perturbation produced in the animal economy of the operated be of such a nature, as to compromise the result of the operation, and to aggravate its consequences. This is what is stated by the opponents of the ether method in France. The most obvious way of resolving this question is to ascertain the number of cases, where either recovery or death has followed operations, and to see what ratio other operations bear to those undertaken without it—not including, however, mesmeric operations in this calculation. The most accurate statistics hitherto attainable on other operations which have ended fatally are comprised in the following table:—

Amputation of femur	4
" " tibia	3
" " arm	2

Amputation of forearm	2
" " toe	1
" " finger	1
" " breast	3
Extirpation of tumour	8

Total

18
If we compare these results with those given by M. Malgaigne, in his "Etudes Statiques sur les Résultats des Grandes Opérations dans les Hôpitaux de Paris" ("Archives de Médecine," 1842), we shall find that, from the 1st of January, 1836, to the 1st of January, 1841, there have been made in the hospital 852 amputations, comprising those from the disarticulation of the femur to the cutting off the joints of fingers. The general mortality of those patients was 332, or a proportion of 2:5. Making the same calculation with ether operations, and taking off that number, those dead after amputation of the breasts and extirpation of tumour, we shall arrive at a proportion of 1:1—favourable, as far as it goes, to ether. Still, as M. Malgaigne says, generalities are often deceiving, and we have to distinguish, in the first instance, between great and small amputations. If we take, therefore, the total number of amputations of the femur, leg, arm, and forearm, we will have twenty-three operations, amongst which ten are fatal, and therefore, a proportion of 2:5. The statistics of M. Malgaigne give, on the other hand, 615 amputations of the same kind, and about 281 deaths, consequently 3:5. These are some approximate data to be arrived at, at present, on a subject, which we believe worthy to be treated by some one well cognizant of the great bearings of medicine as an exponent of the condition and the whole state of mankind.—J. L.—Y.

REVIEWS.

On the Correlation of Physical Forces. By W. R. GROSS, M.A., F.R.S. 8vo., pp. 52. London: Highley, 1846.

The object of this pamphlet, as its title expresses, is to show the reciprocal production or convertibility of the chief physical forces known to exist—to show, in fact, that each force is capable of producing, or being converted into, or of being produced by, every other.

The imponderable agencies selected by our author for the subject of inquiry are, heat, light, electricity, magnetism, chemical affinity, and motion. These, he proceeds to prove, are all correlative, or have a mutual dependence—"that neither, taken abstractedly, can be said to be the essential or proximate cause of the others, but that either may, as a force, produce, or be convertible into, the other; thus, heat may, mediately or immediately, produce electricity, electricity may produce heat, and so of the rest." (P. 8.)

Commencing with motion, the Newtonian proposition is started, that a body, made to move, will continue to do so for ever, and in the same direction, and with the same velocity, unless some contrary force or impediment prevent it. The general opinion is, that, when the opposing forces are equal, perfect neutrality is produced, or that the motion is annihilated. The opinion of our author is, that the force is not destroyed, but merely divided and subdivided, or altered in character. In the one case it is not lost, but perpetuated in a degree inappreciable, yet still really perpetuated; in the other, the phenomenon is maintained, but in a different form of manifestation. The first of these positions is one that has long had the credence of a certain class of philosophers. Mr. Babbage has carried out the idea that a part of our punishment hereafter will consist in hearing the endless reverberation of the foolish or wicked language we may have uttered in our lifetime.

If we imagine the soul, in an after stage of our existence, connected with a bodily organ of hearing so sensitive as to vibrate with motions of the air even of infinitesimal force, and if it be

still within the precincts of its ancient abode, all the accumulated words pronounced from the creation of mankind will fall at once on that ear. Imagine, in addition, a power of directing the attention of that organ entirely to any one class of those vibrations, then will the apparent confusion vanish at once; and the punished offender may still hear vibrating on his ear the very words uttered, perhaps thousands of centuries before, which at once caused and registered his own condemnation."—"Ninth Bridgewater Treatise," p. 148.)

According to Mr. Grove, when motion is met by counter-motion, and a seeming quiescence is produced, leading to the popular belief that the force is annihilated, it is really not so; but ends in the production of another force, which is heat.

"I venture to regard the heat which results from friction or percussion as a continuance of the force which was previously associated with the moving body, and which, when this impinges on another body, ceasing to exist as gross palpable motion, continues to exist as heat."—(Pp. 9, 10.)

If the bodies mutually impinging be homogeneous, heat alone is produced; if heterogeneous, electricity. It results from experiment that when perfectly homogeneous bodies (at least, bodies as fully so as we can obtain and appreciate) are rubbed together, the resulting development is heat only. Whatever slight electrical current might accompany this, would be due to the absence of perfect homogeneity, because, to secure this, the opposing bodies must have no dissimilarity in any single chemical or physical attribute. To secure an identity so perfect is next to impossible: yet it has been secured sufficiently so, in various experiments, to establish the truth of the proposition. On the contrary, if the bodies be distinctly heterogeneous, electricity is the result of their forcible contact; and not only so, but the electricity is the greater, and the heat less, in proportion to the dissimilarity of the bodies.

"Thus, the friction of similar metals gives little electricity; that of dissimilar metals more; and that of a metal and glass still more, as in the common electrical machine, the action of which is so greatly exalted by the metal mercury." (P. 13.)

Having thus far shown that motion will produce heat and electricity, Mr. Grove next passes on to prove that the latter will produce magnetism—"a force which is always developed by electrical currents, at right angles to the direction of those currents."

"Light, again, is readily produced by motion, either directly, as when accompanying the heat of friction, or mediately by the electricity resulting from motion, as in the electrical spark." (Pp. 13, 14.)

"In the decompositions and compositions which the terminal points proceeding from the conductors of an electrical machine develop, when immersed in different chemical media, we get the production of chemical affinity by electricity, of which motion is the initial source. Lastly, motion may be again reproduced by the forces which have emanated from motion: thus, the divergence of the electrometer, the revolution of the electrical wheel, the deflection of the magnetic needle, are palpable movements, reproduced by the intermediate modes of force, which have themselves been originated by motion."—(P. 14.)

These are the leading features and objects of this excellent little treatise. We could have wished that our author had dwelt longer, and with illustrations, upon the influences of light and magnetism. That the latter will produce heat, and light, and motion, we know; but we are not so certain of the correlative powers of the former. Will light, simply such, produce heat, or motion, or magnetism? We doubt whether there are any experiments sufficiently conclusive to justify us in saying so. We wish our author would find time to reconsider this part of a subject, of which he is a consummate

master, and upon which he has discoursed with a rare scholarship and scientific precision.

Body and Soul; or Life, Mind, and Matter. By GEORGE REDFORD, M.R.C.S. London: John Churchill, 1847. 8vo., pp. 232.

This essay does not affect to advance anything new on the complicated and difficult subject it embraces; but rather purposes to be a recapitulation, condensation, and clear arrangement, of the facts previously enunciated at different times, by physiologists and metaphysicians. If Mr. Redford have not introduced to us any novel views or discoveries, at least he has not been wanting in the laudable purpose of judiciously collating and deducting from the established views of other writers. In the execution of his difficult task, he has displayed a great amount of industry, nice discrimination in the selection and disposition of his facts, and a very clear, impartial method of judging of them.

His work is an excellent summary of opinions, physiological and psychological, on the mysterious compound called man, and well worthy the perusal of whomsoever may feel interested in the subject of life and organization.

The Microscopic Anatomy of the Human Body, in Health and Disease. By ARTHUR HILL HASSALL. London: Highley.

We have received of this admirable work the several parts up to February of this year. It is a work of sufficient interest and value to merit, not merely a passing compliment, but a substantial, searching inquiry and criticism. This, we are fully assured, it will not only bear, but be the better for; we shall, therefore, postpone our further observations upon Mr. Hassall's excellent series until they shall have been completed, when it will be our great pleasure to give them the analytical notice their many merits will entitle them to.

THE MEDICAL TIMES.

SATURDAY, APRIL 17, 1847.

MEDICAL REFORM IN 1847.

It must be admitted there is much truth in that oft-repeated saying, "We live in an age of wonders." Novelties multiply around us, and so rapidly do they succeed each other that what attracted our attention and excited our admiration but yesterday, ceases to do so to-day, because of something more extraordinary demanding our regard. Even steam is in danger of settling down amongst those things which we can praise without feeling, and use without gratitude: for the smoke, the hiss, and rattle of the train have long since ceased to make a single horse prick his ears, or a single calf cock his tail, as he grazes in the pastures through which the road has taken its course.

The past week will be memorable in the annals of our profession, not for any new discovery in medicine or its collateral sciences, but from the development of a principle which, till very lately, was supposed to have no existence amongst us—that of brotherly affection. On Tuesday evening the Hanover-square Rooms were graced with a large number of medical men, the majority being general practitioners in medicine, surgery, and midwifery, who were met for social intercourse and scientific converse. Such a meeting is a novelty amongst us, and, being new, it tells of past division, while it cheer-

ingly announces future concord. Many eyes have been turned towards that assemblage, and many hearts have felt strange and opposite emotions about it. The enemies of the general practitioner will denounce it as worthless—his friends will view it as an omen for good. The colleges will frown upon it in their anger, though they may affect to treat it with silent contempt—the pseudo-reformers will watch their opportunity to prick at it with an obsolete instrument, once used but for no higher purpose than phlebotomy. The "getting up" of such a meeting is no easy task; and to the officers of the National Institute the credit is due—they have taken a step in the right direction, while they have given to the profession a pledge of future activity in its service. We have on a former occasion cautioned them against falling into that error which has been so palpably manifest in chartered colleges, and even benevolent institutions; and, as our admonitions were taken in good part, we would entreat them once more to be encouraged by the result of this effort, and to guard against the besetting sin of inactivity, and with energy carry on the good work which has been so creditably begun.

We have before stated that the meeting was principally composed of gentlemen who practise the three branches of the profession, medicine, surgery, and midwifery; and it is a matter of utter astonishment to us that there could be found any one with sufficient impudence to ridicule the idea of these departments of the profession being united, or of sufficient cruelty to attempt the ruin of those who have studied, and who practise, the "healing art" in its different branches. Ridicule is a pretty weapon, when there is none other to employ, and when there is some weakness in the party using it which it is desirable to conceal. And who are those who would cast opprobrium on the general practitioner, and who have endeavoured so to degrade him as to make him a mere tool in the hands of others? They are two orders of men rejoicing under one particular title—"pure." One is so pure that an individual of the class could not for the life of him, nay, nor for that of a friend, use a knife professionally, except it were to trim his pen for writing a guinea prescription; and the other is so pure that, "throwing physic to the dogs," he will hold fellowship only with plaisters, bandages, knives, and forceps. Now, the investigation of truth is one of the most interesting employments in which an intelligent mind can be engaged, and the more extensively and widely it is studied the more exalted and expanded must the intellect become. If this proposition be correct, the general practitioner, *ceteris paribus*, may stand vastly superior to the man who simply confines his studies to the mechanical or empirical part of the profession. We grant that the pure surgeon may become a better handicraftsman; but with nerve and anatomy only, he may make a good hospital surgeon, and shine as a star of the first magnitude in the hemisphere of Lincoln's-inn-fields. That amount of knowledge which the general practitioner must necessarily possess is not required for him; and, if men were to be put in their

the head-quarters of the College would be tenanted by those who, to the present moment, have been ignominiously excluded, even the celebrated John Hunter, himself being judge. This illustrious individual, lauded annually by "pure" orators—furnishing them, through the liberality of Parliament, with a peerless museum—was himself a general practitioner, and has recorded his testimony, that the operative part of the profession shows our limited acquirements; and that for individuals to confine themselves to this part alone is dangerous to the limbs, if not to the lives, of the subjects of the commonwealth. Many curious instances of the reckless use of the knife are recorded in connection with his times. One one occasion, the surgeon waiting in the operating-theatre for a patient who was to have his leg amputated, becoming impatient, sent the surgeon-man in quest of the unfortunate sufferer, when, lo! he returned with the astounding intelligence that the invalid had bolted, using the condemned limb with the agility of a grey-hound. On another occasion the doctor, meeting a tar who had suffered the pangs of amputation, said to him, "Well Jack, you have lost your leg?" "Yes," was the reply. "But how was that?" The son of Neptune, hitching up his trousers and turning his quid, responded "I don't know, your honour; you must ask the doctor!"

One word more, and we have done for the present with these "pure" surgical gentlemen, and that is in reference to the contempt they have manifested for the practice of midwifery. What! is there no room for the exercise of skill, of patience, or of kindly feeling by the accoucheur, when called to the bedside of her "who is in travail, and cries with pain to be delivered"? The terrors which the patient then feels, and the danger in which she is often placed, require that the medical attendant should possess and use the highest endowments of the human mind. We would have these scorners understand that the day is long past since an episcopal mandate was sufficient authority for old women to practise, and that midwifery is now an inseparable and honourable branch of the medical profession.

Nor can we see that the "pure" physician has any better reason for contemning the general practitioner than the surgeon who eschews pills and draughts. We admit that "medicine doctor" is a very imposing title, and might, with a little good legislation, be made a very valuable one; but we do not opine that at present it is all that the public think it is, or that the possessor would have us suppose it is. To be of sterling worth it must have inseparably attached to it age, experience, and intellect. The physician ought to be, and eventually will be, the presbyter of medicine—the general practitioner—mellowed by time, and enriched by hard-earned experience.

There are signs which admonish us that a crisis is not far distant, and it is our earnest wish that those whose cause we now advocate should be fully prepared to meet it. Our advocacy of one order of the profession arises from a desire to benefit the whole. The

general practitioners have been long injured, and we sincerely hope that the Government will not be backward in doing them all the justice to which they are entitled. In the meantime, let them look well to themselves. Their honour and respectability require that to the active engagements of life there should be joined close reading and close thinking; then will they be fortified for any exigency that may arise, and entitled to the highest honours which the Executive can bestow.

THE BURTON-ON-IRWELL POISONING CASE.

We are informed by Baron Humboldt, that in some parts of Spanish South America, where any admixture of negro blood is thought to imply a taint—although, by the agency of a tropical sun, Caucasian and Ethiopian are both equally black—that a judicial investigation is not unfrequently had recourse to for the purpose of determining the important points of blood and descent; and that frequently some haughty senor, with black crisped hair and swarthy skin, displays a document signed by a neighbouring magistrate, to certify that Senior So-and-so may consider himself a white man. And a white man forthwith he believes himself to be,—and was he to the nigger who disbelieves the same! Judicial wisdom, then, is a powerful thing in its way—a thing not to be profanely reasoned on, but believed—implicitly believed as something omnipotent. Every fact drawn from this most honoured source should be religiously preserved and chronicled—held to be a precedent for future reference and instruction.

The omnipotence of a judicial verdict in subverting the ordinary laws of nature is strikingly exemplified in the result of the late trial of Mrs. Johnson, on the charge of poisoning her husband; and we may say the trial of Mr. Leigh, for incompetency as a chemical analyst, for virtually, although not literally, this question was *sub judice* too.

As the facts of this case may possibly not be known to some of our readers, we refer them to a letter from Dr. Scoffern, which appears in another part of the current number. From a perusal of this, it will be seen that a woman and her husband had for some time been living on very bad terms—frequent quarrels took place between them,—in the course of which the woman was heard to wish her husband dead, to threaten to poison him, to promise him a cheap funeral, and the like. She was known, moreover, to have been carrying on for some considerable time an intercourse of great profligacy with another man, who had been seen with her at times, and under circumstances, which placed suspicion beyond a doubt. She was proved to have availed herself of the remarkable facilities afforded by our Legislature for the purchase of arsenic, as on the 27th of November she bought threepenny worth of this poison. On the same day her husband was afflicted with all the symptoms of arsenical poisoning, and on the 3rd of December he died—the almost exact time of his decease having been foretold

by his wife, who predicted that he would never come out of his bed alive. On the day following his death, Mr. Henworth, the surgeon in attendance, called in Mr. Leigh, lecturer on forensic medicine at the Pine-street Medical School, Manchester, to assist him in making an analysis of the contents of the stomach; which analysis was accordingly made; and this latter gentleman—the sole responsible party as to chemistry, in the present case—obtained by Reinsch's test some metallic stains of which he could not determine whether they were produced by arsenic or by antimony! The body thereupon was interred, and thus affairs remained until the beginning of March, when, for some reason which does not seem to have transpired, the corpse was now disinterred, and Mr. Leigh, the professor of organic chemistry and toxicology at a medical school, called in Mr. Watson to assist him in repeating the analysis; which seems to have been conducted in a very careful manner. This time the presence of arsenic was determined in very considerable quantities—not only by Marsh's and Reinsch's tests, but also by the less delicate liquid tests. Assuredly then Mrs. Johnson's friends must have considered her case very bad, and Mr. Leigh's friends must have regarded him as labouring under an imputation of incompetency.

Mrs. Johnson was acquitted, however—and with her—the toxicological professor. It was argued by the prisoner's counsel, that inasmuch as the presence of arsenic had not been satisfactorily determined by Mr. Leigh on the 4th of December, before the corpse had been interred, but had been discovered in considerable quantity in the beginning of March by Mr. Watson, after the corpse had been disinterred,—that the arsenic thus found had been *washed into the body* by some water found in the grave! This judicially-determined fact we need hardly say is not more extraordinary than important. Had it not been established to the conviction of a British jury, Mrs. Johnson's love for her paramour would have had an unpleasant quietus; and Mr. Leigh's chemical acumen would not have been above suspicion. He may now show his judicial certificate and say—I am a white man.

[Would any correspondent favour us with a portion of the churchyard soil for analysis? It must be rich in arsenic.]

MANCHESTER ROYAL INFIRMARY.

An election for one of the surgeons of this institution has just been contested between Mr. N. Beevor and Mr. Smith. The latter gentleman was nephew to Thomas Turner, Esq., himself, for a long period, one of the surgeons to the establishment; but still Mr. Beevor was the winner by sixty-nine votes. We are not sorry for this, on other grounds than the merits of the candidates. We do know that the ruin of more than one hospital in London and elsewhere has been consummated by nepotism. The sons and nephews of the present officers are thrust into place and responsibility at an age and with an inexperience fatal to usefulness. We take the present defeat of the re-

presentatives of nepotist influence as a pleasing augury that a certain portion of the public at least desire to do their duty to the Manchester community. The trustees of this infirmary will, we believe, shortly have another opportunity of evidencing their public spirit in this direction; and knowing the high classical and scientific attainments of some of the medical staff, and particularly its consulting officers, we expect the best results. There exists a rule, or by-law, established many years ago, to meet a very particular case, but which has not been since rescinded, insisting that any candidate for the office of physician shall produce proof of long collegiate residence at the place where he may have obtained his diploma—a rule which, of course, excludes nearly all licentiates of the College of Physicians, London, as well as all those who have been educated at one establishment, and by virtue of that education obtained their degrees at another. This is manifestly an injustice, which, we trust, will be speedily remedied. It is bad to the profession: it is, if possible, worse for the public. It is a close-borough system which should not exist in science.

THE NATIONAL INSTITUTE OF MEDICINE, SURGERY, AND MIDWIFERY.

On Tuesday, the 13th instant, a *conversazione* of the members of the National Institute of Medicine, Surgery, and Midwifery, was held at the Hanover-square Rooms, which was attended by a numerous assemblage of both metropolitan and provincial members. Among the latter we noticed Messrs. Beddingfield, of Stowmarket; Stedman, of Guildford, Surrey; Chesterman, of Banbury, Oxon.; Warner, Cirencester; Stilwell, of Epsom; Wallace, of Carlisle; Thos. Martin and V. Martin, of Reigate; Daniells, of Newport Pagnell; Thompson, of Westerham, Kent; Pout, of Yalding; Snell, of Milton-Abbot, Cornwall; Hennings, of Kimbolton, Hants; Napper, of Guildford; Barnett, of Alton, Hants; Haines, of Pinner; Mackinlay, of Isleworth; Crocane, of Horsham; Sturton, of Greenwich; Westall, of Craydon; Collins, of Kington, Devon; Paget, of Leicester; Swaine, of Birmingham; Day, of Isleworth; Baker, of Bedford; Bennett, of Wintertown Barton, Lincoln; Dalrymple, of Norwich; Curtis, of Alton, Hants; Parker, of Woburn, Beds; Anson Cartwright, of Teignmouth, Devonshire.

For the gratification of the gentlemen present on the occasion, the council had invited collections of subjects of great curiosity, interest, and value, which were displayed on tables down the middle of the great room. Among these were instruments for the inhalation of ether and of oxygen; admirable models of pathological subjects, after the invention of Dr. Thibert; a great many specimens of articles of the *materia medica*, remarkable for purity and superiority of quality and character; and there was a collection of engravings and curious objects of *virtu*, referring to the archaeology of medicine, the property of G. J. Squibb, Esq. This collection comprises the largest number of portraits of eminent medical men of all ages and countries which is known to exist.

Mr. Ward, of Wellese-square, exhibited many interesting natural curiosities, and also one of his close cases for the culture of plants; and kindly gave a short history of his discovery of this most agreeable and useful adjunct to the cultivation and preservation of plants in an atmosphere so unfavourable as that of the metropolis, and also as respects great diversities of temperature.

Mr. Ward, after citing the elegant hypothe-

tical description of the physical peculiarities of climate in Paradise, stated, that, supposing the description to be probable, it was not unreasonable to conclude that the atmosphere and climate of his case might be nearly those of Paradise itself.

Following up the analogy, Mr. Ward did not doubt that apartments for human habitation might be similarly adapted for the occupation of invalids suffering from pulmonary and cutaneous diseases; mentioning the instance of a lady who, having been ordered to a warmer climate, from circumstances being unable, as well as unwilling, to leave home, rooms were adapted for her use on the principle, in which, after living for one or two years, she was perfectly restored to health. It is well known that the principle of Mr. Ward's cases is to secure a perfect stagnation of the air and a perpetual moisture.

In the course of the evening Mr. PENNINGTON, the venerable and highly respected President of the Institute, delivered the following address.

"GENTLEMEN.—After difficulties innumerable, we have at length arrived at a period in the history of the NATIONAL INSTITUTE which I trust will be an evidence of two things:—1st. That as a class we are determined to sustain our position, and to assert with becoming dignity our right to be considered one of the scientific bodies of the kingdom, and an essential part of the medical profession.—2nd. That as general practitioners, hitherto in possession of no means of social communion, we are resolved to furnish them for ourselves, and no longer to be solely dependent upon the courtesy of other bodies.

"I have been sixty years a member of the College of Surgeons. I believe that I am the oldest member of that body, and I fearlessly assert that no man has had better opportunities of judging than I have respecting all that is connected with our profession, and of the various relations of that profession to the public. My intercourse with every order of medical practitioners during this long series of years, and my enjoyment, I may fairly say, of a very considerable share of the public confidence, has afforded me means more extensive than has fallen to the lot of any other individual, not only of judging what the medical requirements of the community are, but also of the capabilities of every description of medical practitioner.

"You are all aware, gentlemen, that during the whole of my life I have practised as a general practitioner. Cullen, William Hunter, Jenner, and Abercrombie, were general practitioners, and we have a right to feel proud of the memory of such names. Throughout the lengthened period to which I have referred, I have had the most complete demonstration that the confidence reposed by the public in the competency and skill of the general practitioner has been well merited, and that the principles upon which the general practitioner stands are those of truth and justice; and my connection with the National Association and the National Institute has assured me, that this confidence not only continues, but is on the increase, and that I and others, who must soon pass from the scene, will be followed by gentlemen who will equally enjoy it, and who, in the progressive advancement of practical medical and surgical science, will fully sustain the character and the honour of their class.

"Identified as I have been with this class—impressed with the most thorough conviction that the welfare of the community depends upon its prosperity—observing its progressive advancement in knowledge and respectability—it has for many years been a source of deep regret to me, that so large and intelligent a body, embracing as it does so much sterling worth, should be deprived of the advantages which would result to themselves, to science, and to the public, from their association into an effective and permanent body; by which association only, can they take their stand as one of the recognised medical institutions of the country.

"My energies have ever been directed to the attainment of this object. I took an active part

during the agitation of the years 1812, 1813, 1814, and 1815. With this object in view, I failed with satisfaction the attainment of the Act of 1815. Defective as it was, the act gave to the general practitioner the power of educating himself up to the standard which his important functions demanded. From that time to the present, and totally apart from any bill introduced by any Minister, I have never failed to advocate the INCORPORATION OF THE GENERAL PRACTITIONERS, and the retaining this power in their own hands, and extending and perpetuating this important privilege. It was the contemplated abrogation of this privilege, and the tendency to lower the social and professional position of the general practitioner, and thereby to inflict a serious injury upon my fellow-creatures, in the change recently adopted by the College of Surgeons, and in the medical legislation recently attempted, which induced me, at my advanced period of life, again to take an active part in asserting the claims to consideration of the class to which I belong.

"Personally I have no interest in the matter. My comfort and convenience would have been better consulted by ease and retirement—taking no part whatever in political agitation. Still, I by no means regret the part I have taken; and I here again declare my unflinching determination to do all that lies in my power, by every means that can be suggested, and to the latest day of my life, to accomplish the object which we have so much at heart,—an object which, for my mind, involves the security and happiness of the whole community. At the same time I should not be doing you justice if I hesitated to express my deep regret and great disappointment at the apathy, distrust, and lukewarm spirit with which the profession has regarded objects so highly important both to themselves and the community; and that out of a body numbering perhaps 12,000 or 15,000 individuals, only 4000 have as yet been found public-spirited enough to enrol their names as opponents of a scheme of legislation based upon the most erroneous principles, while a still smaller number have come forward to co-operate actively to promote a just and beneficial measure of MEDICAL REFORM.

"Notwithstanding all this, I live in hope of better things. The National Institute will try and carry through its plans in the face of every discouragement or difficulty which may present itself. It is contemplated immediately to take a house as a permanent abode. The representative council will be annually renewed,—we shall hold our general, our scientific, and our social meetings,—we have already commenced a collection of books, and a large and valuable library will be doubtless formed with great rapidity,—a museum will be the next object of our solicitude; and I trust that, before long, we shall be enabled to give substantial encouragement to the members of the Institute for contributions to science. A great object of the present meeting has been to bring together the PROVINCIAL and the METROPOLITAN MEMBERS, that they may have the opportunity of communing freely with each other upon all these subjects, and upon any and every other subject which may bear upon their political and social welfare, and for the especial purpose of promoting the greatest desideratum of all—a mutual good understanding.

"I have not deemed it right, gentlemen, to occupy your time, upon the present occasion, by any lengthy address; but I was anxious to avail myself of the opportunity, to make my own views and my own determination well understood, and for that purpose I have had these few observations printed, that any gentlemen who desire them may have copies for themselves, or for those friends who are not present, and that no misapprehension may arise from any imperfection in my delivery. I will conclude by stating, that upon this first occasion, the council has laboured under great disadvantages, owing to our not having rooms of our own; but, for the purpose of showing what the nature of our social meetings will be, they have hastily collected together a few objects of interest. I hope every one present

will pass the evening agreeably, and to the advantage of the cause in which we are engaged; and I trust that we shall separate with a renewed determination to employ our utmost zeal and energy to promote the successful issue of the cause."

The conclusion of this address was followed by the unanimous expression of warm applause, and a resolution of thanks was carried by acclamation.

The usual refreshments were at hand, in the adjoining room; all appeared to enjoy the utmost satisfaction in the proceedings of the evening, and separated with an assured confidence in the expectation of the enjoyment of similar reunions at future times, with improved and enlarged appliances and means of social and intellectual enjoyment.

INFRINGEMENT OF THE APOTHECARIES' ACT.

Ellis Flitcroft, a bricklayer by trade, but now a shopkeeper, residing in Boardman-field, was indicted at the Bolton Quarter Sessions, on Saturday, April 3, for misdemeanour, having practised as an apothecary without a certificate. Mr. Brandt conducted the prosecution, instructed by Mr. John Gaskell, the public prosecutor; and Mr. Sowler appeared for the defendant, instructed by Mr. Richardson, solicitor.

Mr. Brandt, in opening the case, called the attention of the jury to the indictment, which was of a different character from any that had previously been before them. The charge was made under the 55th Geo. III., c. 194, the fourteenth section of which prohibited parties from practising as apothecaries without being duly qualified by a certificate from the Apothecaries' Company. The learned counsel then detailed the facts as given in evidence, and referred to two cases in which convictions had taken place under similar circumstances. These were—the Apothecaries' Company v. Allen, reported in "Barnwell and Adolphus," vol. 4, p. 625; and Woodward v. Ball, in "Carrington and Payne," vol. 6, p. 577. He then called the following witnesses:—

Lettice Bartley, wife of Thomas Bartley, said: On the 7th of December last I was living in Bolton. My son Robert was ill at the time. He was seventeen months old. I know the defendant, Ellis Flitcroft. I went to him on the 8th of December, at his house in Boardman-field. I saw him there, and told him about my child. I said it was very poorly, and very red in its cheeks. Flitcroft said his child would have been in its grave but for Dr. Coffin's medicine. I told him there were three of my mother's children ill at the same time. He said that if they were red in the cheeks, and there were three of them down beside mine, it would be scarlet fever. He sold me 1½d. worth of what he called raspberry leaves, and told me to get one pennyworth of pennyroyal, and mix them together. Afterwards he came to my mother's house, and brought a bottle with him. I got him some boiling water, and he mixed some medicine for the child, which I gave to it. He said the medicine was to make it sweat. My mother also gave some of it to her children. Flitcroft said it would do them good: it would warm them. He also gave me a bottle of stuff; but it was not so terribly strong. I tasted it, and found it mild. It was to be given to the child a teaspoonful every twenty minutes. He said it was to make the child sick. I gave it to the child every twenty minutes till about seven o'clock at night. The medicine did not sweat the child: it became very sick, but could not vomit. Flitcroft came to my mother's house at dinner time, and applied a bottle of hot water to the child's feet and back. At eight o'clock the same night I went to his house again. He was not in, but I saw his wife, and she gave me some medicine for the child. I gave it the day after, and I told him his wife had given me something for the child. I tasted it, and found it very hot. The next

day he came again, between two and three o'clock in the afternoon, but did not bring any medicine. He then told me to put the child in a warm bath, and to give it the medicine his wife had given me once every hour. I did so, but the child grew worse. I went to his house again on the Friday, and he gave me something to make the child vomit. It was in a bottle. A powder was sent up the same night, but I did not give it to the child. The stuff that was left in the bottle was given to Mr. Denham, surgeon. He charged 1s. 9d. for what I had from him on the Friday, but I paid nothing; 1½d. for the raspberry leaves.—By Mr. Sowler: Flitcroft is known in the town as agent or assistant to Dr. Coffin, the herbalist. I never saw Dr. Coffin.—By Mr. Brandt: She has seen the coffin, but not the doctor.—(Laughter).—By Mr. Sowler: I did not give the child the medicine sent on the Friday night. I gave it a pennyworth of "white wine pick" (emetic), which made the child sick, the same as Flitcroft's medicine, but it could not vomit. I went to Mr. Challoner, druggist, on Saturday, and got half an ounce of castor oil and syrup of rhubarb, which I gave to the child at ten o'clock in the morning. It was very thirsty, and I gave it some hyssop tea about half-past five in the afternoon. This was the last thing it had.—Alice Grundy, mother of the last witness, deposed as follows: I remember Flitcroft coming to see my daughter's child; he brought a bottle with him. I had three children ill at the same time of scarlet fever. Flitcroft looked at them, and said one was very ill, and would go off in a decline if she did not get some help.—(Laughter). He said he would engage them at half-a-crown a piece.—(Laughter). I did not approve of it. He sent a bottle for my eldest child, and I gave her part of it. As soon as the girl got it, she screamed and said, "Mother, it is burning my throat." It was part of what my daughter's young child had taken. After the girl took it she became more red in the face, and I had no more of his stuff, but sent for a medical man, and my children got well.—By Mr. Sowler: Flitcroft is known as the agent of Dr. Coffin. I never saw Dr. Coffin, but my son heard him lecture in the Temperance-hall, and was in a great passion at him.—(Laughter).—Susannah Greenhalgh gave the following testimony: I am the widow of George Greenhalgh, who died on the 16th of January last, aged twenty-five years. He left work on Thursday, the 7th of January, and the next day he brought home a bottle of medicine, which he took every four hours. At first he thought it did him good, but the next Tuesday he was much worse. On Wednesday he was bedfast, and sent for Flitcroft, who came and saw him in bed. He ordered me to get a vinegar cloth and apply it, with a bottle of hot water, to my husband's feet. He also told me to come to his house for some medicine, which he said was to sweat, and pick, and purge my husband. I went to his house and received two powders, one of which was green and the other buff. He charged me fourpence for them. Of the green powder my husband was to take nearly a teaspoonful mixed in warm water with sugar to sweeten it. The buff one was to be mixed two teaspoonfuls in a gill and a noggin of warm water, of which he was to have not quite a teaspoonful every twenty minutes. This my husband took twice, but would have it no more. He grew gradually worse, and died on the 16th of Jan. Margaret Rogerson was at our house, and gave part of the powders to Finnigan, the police-officer. A man named Grady died in the same street, but Flitcroft did not tell me he was attending him.—By Mr. Sowler: My husband thought the medicine did him good the first day or two. Flitcroft told my husband he must not go to work, for he was not strong enough. He went, however, on Tuesday, and worked three quarters of a day, and on Wednesday he was bedfast.—Margaret Rogerson said: I saw the husband of the last witness in bed on the Thursday. He appeared to be in great pain. He told me he had been taking some of Dr. Coffin's medicine. I said to him, "George, I believe it is killing thee;" and

he replied that he would take no more. He was very thirsty. Some of the powders that were left I gave to Finnigan, the policeman.—Mrs. Leach, wife of John Leach, boerseller, said: About two months ago I had an attack of rheumatism. I consulted Flitcroft, and he sent me a powder and a bottle. He came to the house and saw me. I took the powder. It was very warm, and I would take no more. I took one glass of the bottle, and no more.—By Mr. Sowler: I cannot say that the medicine did me either good or harm. I got better; but it was Dr. Chadwick that cured me. I have seen the defendant's sign: the words upon it are, "James Flitcroft, vender of herbs, from America; licensed to sell tea and coffee."—(Great laughter).—Martin Finnigan, sergeant of the borough police, examined by Mr. Brandt: I am acquainted with Ellis Flitcroft, the "vender of herbs, from America." I first know him five or six years ago, when he joined the police force. He is a bricksetter by trade. I received some powders from Margaret Rogerson, which I gave to the coroner.—By Mr. Sowler: I am the coroner's officer, and it is my duty to look after evidence when an inquest is to be held. I lodged the information against Flitcroft, under the direction of Mr. John Gaskell, the public prosecutor. All the witnesses, except Mrs. Leach and Mrs. Grundy, were examined by the coroner.—Thomas Mewburn, sergeant of police, said: I apprehended Flitcroft on the 28th of January, and read the warrant over to him. He said he had no certificate, and did not require one; that he was not an apothecary, as he only dealt in herbs and plants.—Mr. Taylor, borough coroner, produced the powders given to him by M. Finnigan, and said that they had been examined by Mr. Denham, surgeon.—Cross-examined by Mr. Sowler: I have not taken any active part in getting a case against Flitcroft. I may have said something to Mr. Harris on the subject. I do not remember saying to him that I had found out some old law that would put Flitcroft down. The clause in the Apothecaries' Act under which Flitcroft is indicted is not old, and I have known it for several years.—Mr. Denham, surgeon, said: I made a post-mortem examination of the body of Robert Bartley. The child died of inflammation of the lungs. I made the examination under the direction of the coroner. Inflammation of the lungs is a medical case. George Greenhalgh's was also a medical case. The green powder produced by the coroner is lobelia, generally called Indian tobacco. It is a medicine, and inserted in the Materia Medica. It will operate in small doses as an emetic; in large doses, as a purgative; and in very large doses, as a narcotic poison. It would be more injurious from not producing vomiting. The buff powder consists of capsicum, or Cayenne pepper, apparently mixed with some spices. In cases of inflammation it is injurious. It is a medicine unfit for a child seventeen months old under any circumstances. It would produce great thirst. It is a medicine, and in the Materia Medica.—By Mr. Sowler: In small doses capsicum will increase the circulating power. In cases of great debility it is not an improper medicine. Lobelia has been introduced into the Pharmacopoeia, if I recollect rightly, since 1819. It is a vegetable production, and a native of the United States of America. Capsicum is also a vegetable production. Druggists and grocers, I believe, are in the habit of selling it in lozenges.—By Mr. Brandt: The great mass of medicines are derived from vegetables.—By the Recorder: The druggists sell these things to persons who go and ask for them. They do not go out and prescribe.

This closed the case for the prosecution.

Mr. Sowler then addressed the jury on behalf of the defendant. He denied that Flitcroft had acted as an apothecary within the meaning of the act of Parliament. The cases cited by his learned friend were of a totally different nature from this. The parties held themselves out to the world as apothecaries; but in this case the facts were just the reverse. It was clear that Flitcroft did not

profess to be an apothecary, but merely a vender of certain American herbs. His client, therefore, had not been stalling under false colours. He sold medicinal herbs, and persons who purchased them knew that they were herbs. The poor people, unable to obtain the assistance of a surgeon, went to him for medicinal herbs, because they knew that he was the agent of Dr. Coffin. The parties who went to Flitcroft knew very well that they were purchasing Dr. Coffin's herbs; and when Flitcroft called upon them it was not as an apothecary, but as an assistant to Dr. Coffin, the herbalist. The question was, did Flitcroft, as assistant to Dr. Coffin, and administering his herbal preparations, act as an apothecary? He would prove that Flitcroft was the agent of Dr. Coffin, or rather his assistant, and that there were vegetable prescriptions given in Dr. Coffin's book, which Flitcroft and others were able to follow.—Mr. Sowler then called

William Chippendale, who deposed as follows: I am an assistant to Dr. Coffin, of Manchester. He is the author of a work on herbal treatment. [Mr. Sowler here asked the witness to read the title of the pamphlet, but Mr. Brandt said, "No, no, we want no quackery here." An attempt was also made to hand it up to the recorder, but the learned gentleman smiled, saying, "No, thank you, I don't want it."] Flitcroft was appointed assistant for Bolton in November last. Since then he has been at Manchester two or three times a week, and has done different jobs that we have required of him. He has to administer the pepper and lobelia according to the prescription in Dr. Coffin's book. In difficult cases he comes to Manchester to obtain Dr. Coffin's advice. There is not a single mineral used in our practice: only herbs, roots, and barks.—Mr. Brandt: Only "herbs, roots, and barks." But I suppose you can make 1,000 prescriptions from these? Witness: Yes, perhaps we can.—Mr. Brandt: Where did Dr. Coffin get his degree? Witness: In America.—Mr. Brandt: And why is your master not here? Witness: Because he is engaged in Manchester with his patients.

Mr. Sowler then addressed the jury in support of the prosecution. He said the answer attempted to be set up by his learned friend was one of the most extraordinary he (Mr. Brandt) had ever heard. It was attempted to be shown that this bricklayer and ex-policeman was an assistant to Dr. Coffin, and that as such he was entitled to prescribe and administer medicines to those who might consult him! Why, if this were the case, Dr. Coffin or Dr. Death might have assistants in every town and village in the country, provided he could find ignorant people to pass off his "herbs, roots, and barks." But if Flitcroft had really been appointed an assistant, why was Dr. Coffin not here to produce the appointment? Here we have a man treating inflammation of the lungs as scarlet fever. He goes to a house where there are four children apparently in the jaws of death; he does not suggest that a surgeon should be called in, but goes on prescribing till one of them dies, and the answer is that he did not prescribe as an apothecary, but as an agent to a herbalist! The simple question for the jury to decide was, did Flitcroft act as an apothecary? That he had done so there could be no doubt, and he left the matter with the utmost confidence in the hands of the jury.

The Recorder, in recapitulating the evidence, said that Flitcroft was indicted for acting as an apothecary, not having a certificate entitling him to do so. The question was, not whether the medicines had been properly prescribed, but whether, in prescribing them, he acted as an apothecary? The intention of the act was to prevent unskilful persons from acting as apothecaries, to the danger of her Majesty's lieges. The 14th section prohibited any person from practising as an apothecary without a certificate, and that Flitcroft had not a certificate was admitted by himself. His statement was, that he only practised in herbs, and did not, therefore,

require one; and the question for the jury was, whether, in law, he did or did not practise as an apothecary? There was a section in the act imposing a penalty, if the parties had thought proper, but it was equally open to them to proceed as they had done, by indictment. The learned recorder then proceeded to read the evidence, making such comments as he thought necessary; and, in conclusion, he remarked, that their duty was to dismiss all other considerations from their minds, and decide whether or not Flitcroft, in attending the parties and prescribing for them, had acted as an apothecary within the meaning of the act of Parliament.—The jury retired about one o'clock, and returned into court at a quarter past two, when the foreman pronounced a verdict of *Guilty* against Ellis Flitcroft.—Mr. Sowler applied for an arrest of judgment, on the ground that Flitcroft ought to have been charged under the 20th section of the act as an assistant.—The Recorder said an indictment would not lie upon the 20th section. The prohibition was in the 14th, and upon that the indictment must be founded. When an act of Parliament prohibited a person from doing a certain thing, parties offending must be indicted on the prohibitory clause, and not upon those providing punishment.—Mr. Brandt read an extract from Archbold confirming the opinion of the recorder. He also stated that, as the object of the prosecution was to show parties what the law really was, they had no desire to ask any very severe punishment against Flitcroft.—The Recorder then sentenced Flitcroft to one month's imprisonment in the New Bailey.

STATISTICAL SOCIETY.

Colonel Sykes, vice-president of the Royal Society, read a paper on the vital statistics of the East India Company's armies in India, European and native. The documents upon which the paper was founded were of an elaborate nature. Colonel Sykes divided his subject into three distinct sections. The first section comprised the returns of the mortality of the native troops of the Bombay army for the years 1842, 1843, and 1844, at every age, from twenty to fifty-two inclusive. The second section comprised returns to an order of the House of Commons, upon the motion of Mr. Hume, of the sickness, mortality, and invaliding of the Indian army, European and native, for twenty years. The third section comprised the pension establishments of the native armies. It is difficult to give an abstract of a lengthy but important document which was itself but an abstract of an extensive subject, and the tables only can satisfy the inquirer with respect to details. Some facts only fall within our scope. The vital statistics of the Bombay army will create a complete revolution of opinion with respect to the value of native life in India. Tables are constructed, showing the value of life at each age of the troops serving in Scinde, of those not serving in Scinde, and of the whole army. The gross mortality in England and Wales, as exhibited in one of a series of tables submitted to the society, shows that it is coincident with the specific mortality at age thirty-nine; and, assuming that such will also be the case in the other tables, it may be concluded that during the three years, 1842, 1843, and 1844, the mortality of the whole Bombay native army, including that in Scinde, was 2.729 per cent., being somewhat greater than that for the city of Glasgow at age thirty-nine, which is 2.410 per cent.

But, taking the whole Bombay army for twenty years, the mortality is only 1.901 per cent. per annum. Another important result arrived at, is the removal of all rational grounds for the terror which has hitherto obtained re-

specting the intensity and extent of Asiatic cholera. The annual average strength of the whole Indian army for twenty years was 12,028 Europeans, and 104,082 natives. The annual average loss for cholera for twenty years was—

	Europeans.	Natives.
Bengal	51	224
Madras	22	348
Bombay	14	90
Total for India	87	662

The per centage annual loss, therefore, for Europeans was less than three quarters per cent., and that of natives only one-third per cent. The recent details from one locality in Scinde struck the public mind in India and Europe with amazement and horror; and such impressions would be justifiable were these visitations to be of frequent or extended occurrence, but the experience of twenty years relieves us from our alarms. For the annual average loss of European soldiers for all India was only 724 per cent., and of native soldiers only 342 per cent. The maximum strength of the European portion of the Bengal army in 1844 was 5034; the minimum strength in 1827 being 3793 men. The maximum admissions into hospital were 11,202 in 1841, out of a strength of 4751, so that each soldier on an average was more than twice in hospital during the year, and some three times. The minimum admissions into hospital occurred in 1827 being only 927 out of a strength of 3793, so that not every fourth man went into hospital, although the mortality that year was great, amounting to 8½ per cent., and the invaliding to 6½ per cent. The maximum deaths from ordinary causes occurred in 1825 being 539 from a strength of 4512, producing the maximum mortality of the twenty years, namely, 12½ per cent.; the invaliding of that year, however, being only 3.7 per cent. The maximum deaths from cholera occurred in 1843 being 107 from a strength of 5016 or 2.13 per cent. The absolute minimum number of deaths from cholera was in 1826, being 23, or .53 per cent; but the minimum per centage of deaths from strength was in 1830, when, although forty-two died from cholera, the per centage upon strength was only .24. The maximum per centage of ordinary deaths occurred in 1825, when it amounted to 11.94 per cent., cholera only adding a half per cent. The minimum was in 1834, amounting to 4.23 per cent. The maximum for cholera was in 1843, amounting to 2.13 per cent.; and the minimum in 1830, being .24 per cent. The maximum of deaths from all causes was 12½ per cent. in 1835, and the minimum 5.16 in 1829. The greatest invaliding was 6.7 per cent. in 1826, and the least, 1.7 only, in 1835. The mean of the ordinary deaths to the strength for twenty years was 6.23 per cent; from cholera, only 1.15 per cent.; from all causes, 7.38 per cent.; and the mean annual invaliding, 3.6 per cent. The mean per centage of deaths in the European troops of the Bombay army, from ordinary causes, for twenty years, was 4.51; from cholera, .56; and from all causes, 5.07. Comparing the mortality of the European troops of the three presidencies, Bengal loses the greatest number: from ordinary causes 6.23, and from cholera 1.15 per cent.; total, 7.38 per cent. Madras loses the least: from ordinary causes 3.42 per cent., and from cholera .43; total, 3.85 per cent., about the half of that of Bengal. The loss at Bombay, 5.07 per cent., is somewhat more than at Madras. The mean loss of the European troops of all the presidencies is 4.68 per cent. from ordinary causes, .72 from cholera, and from all causes 5.41 per cent. The mean per centage of deaths in the native army of Bombay from ordinary causes was 1.01 per cent.; from cholera, .28; and deaths inclusive of cholera, 1.29 per cent. Comparing the mortality of the native troops of the different armies, from all causes inclusive of cholera, Bombay suffers least, 1.29 per cent.; Madras most, 2.09 per cent.; and Bengal is intermediate, or 1.79 per cent. The remarkable healthiness of the native troops is best shown

By the following sums and means for twenty years:-

Sums.	Admissions into Hospital.	Deaths, Ordinary.	Deaths, Cholera.	Invalid	Per Centage, Death, Ordinary.	Per Centage, Cholera.	Deaths, all Causes.	Per Centage Invaliding.
Bombay	638,375	586,017	6,155	1,796	21,155	1.01	281	3.31
Bengal	9,048,425	1,100,735	32,170	4,688	30,413	1.57	920	1.600
Madras	1,196,360	904,325	18,008	6,976	23,479	1.512	583	1.902
	8,881,660		56,713	13,960	75,077		1,803	1.931

Want of space permits only a bare notice of the pension returns. One explanation will suffice to show the duration of life of the pensioners, and the good effective service they had previously performed. In Bengal, in 1843-4, there were 79 native captains on the pension list who died: their average age at the time of death was 72½; and their average time of service, before going on the pension or invalid list, was 43 years, 5 months, and 3 days. The total number of pensioners on 30th April, 1845, was 33,743, and the annual charge above £190,000. At Madras, at the same date, the number was 27,959, and the charge for them £204,695 per annum.

Colonel Sykes concluded with some observations on the habits and diet of the Europeans and natives, as bearing on health.

MISCELLANEOUS CORRESPONDENCE.

DR. SCOFFERN ON THE BURTON-ON-IRWELL POISONING CASE.

[To the Editor of the Medical Times.]

SIR,—Circumstances having rendered it necessary for me to watch the cases of poisoning which have occurred of late, I have been much struck with what appears to me to be a remarkable acquittal;—an acquittal which must be referred to an assumption which the records of toxicology inform us is wholly gratuitous. I refer to the Burton-on-Irwell case of supposed poisoning by arsenic, which has resulted in the acquittal of Elizabeth Johnson. As some of your readers may have forgotten the leading features of the case, I will take the liberty of very briefly recapitulating them. They are these:—The woman, Elizabeth Johnson, was proved to have lived, for some time preceding his death, on very bad terms with her husband—to have affirmed that she wished him dead—that she would remove him by poison, if driven to extremities. She was proved to have bought arsenic on the 27th day of November—the very day when her husband first began to suffer from symptoms of arsenical poisoning. She was proved to have predicted the night of her husband's death! These facts alone, to say nothing of a profligate intimacy between her and a man called Abraham Hewett, furnished strong presumptive evidence as to her guilt.

The husband dies on the 3rd of December, and on the 4th Mr. Hepworth, the medical gentleman in attendance, calls in another medical gentleman—said to be proficient in chemical analysis.—Mr. Leigh, to assist him in ascertaining whether poison were present. Reinsch's test is used, and a stain results which Mr. Leigh, although a lecturer on organic chemistry and forensic medicine, cannot decide whether it be arsenic or antimony. The body is reinterred, and thus matters remain until the beginning of March, when Mr. Leigh, very prudently doubting the perfection of his analysis, obtains a warrant for the disinterment of the body, and calls in Mr. Watson, an analytic chemist, to assist him in making a fresh chemical examination. This time the presence of arsenic is conclusively established by a number of tests; some of which, as the ammoniacal nitrate of silver, will not act except the poison exist in comparatively large quantities. The counsel for the defence urges a plea that, water having been found in the arsenic might have been conveyed into

the body by percolation; the plea is accepted by the jury, and Johnson is acquitted! Now, although the passing of comments which reflect upon the decision of a jury is a somewhat unthankful office, I cannot help remarking that the supposition involved in this plea is totally at variance with all toxicological records, which bear upon the point.

The increase of poisoning in Britain is frightful; we talk of Toffania and Brinvilliers, but there are individuals now existing in England who far out-Herod them, and so careless is the British Legislature on the protection of human life, that, until a member of Parliament at last falls a victim to the Circean altar of secret poisoning, the evil will be allowed to proceed. You could not, in my humble opinion, better exercise your powerful journal than in drawing legislative attention to this important subject.

I am, Sir, your obedient servant,

30, Essex-street.

JOHN SCOFFERN.

P.S.—I may take this opportunity of remarking that the daily journals of last week would make it appear that Dr. Venables was engaged in the analysis of Dr. Cronin's mixture. This is not the fact; I was appointed to perform the analysis by the coroner, and Dr. Venables was merely present; indeed, Dr. Venables could not delicately have undertaken the task, inasmuch as his son is Dr. Cronin's pupil. It is somewhat singular that Mr. Weather's, the medical gentleman who attended Miss Collier, and myself, who performed the analysis, were not examined at all.

DR. VENABLES ON THE CRONIN CASE.

[To the Editor of the Medical Times.]

SIR,—I feel assured you would not have copied the article in page 143 of your journal of the 10th inst., from the *Pharmaceutical Times*, had you reflected upon its manifest want of candour, or the inherent evidence it presents of the violation of every principle of honour, justice, and truth. It purports to be a comment upon Dr. Cronin's acquittal. In his strictures the writer imputes to Mr. Tennant and myself, as the "friendly advocates" of Dr. Cronin, the suggestion to this gentleman, that the black oxide of iron in Beazeley's compound powder of strychnia would have decomposed the prussic acid in the medicine, &c. Assuming such to be the fact, I see nothing either "dishonest" or discreditable in submitting to a court of law any substantial view or conjecture that may seem calculated to assist the accused. But I cannot say so much in favour of that surreptitious intrusion upon the sacred intercourse between an accused and his confidential advisers which possesses itself of their secrets; much less can I approve that *discretion* which, by divulging, proclaims its own dishonour. In what way the writer became possessed of facts so truly confidential, as to be known only to himself, it is not for me to explain, and the surmise may be left to some abstruse form of "special pleading."

I must, however, in justice exonerate the writer from the inferential consequences of his own self-accusation. From the difficulties encountered by reporters, occasional inaccuracies will find their way into the best reports, and, as unintentional—frequently, indeed, unavoidable—are justly excusable. But what excuse can be urged for the deliberate and wilful perversion, not to say violation, of the truth in the closet? The writer of the article in the *Pharmaceutical Times* asserts that for which there is not the slightest foundation, and which is nothing

more than a mere fabrication. Neither Mr. Tennant nor myself "fixed upon," or ever thought of fixing upon, Beazeley's compound powder of strychnia, as the basis of any "special pleading." Neither was the chemical reaction, so much dwelt upon by the writer, "eagerly laid hold of by Dr. Venables, nor wielded by him in any line of argument." The suggestion of the possibility of such a reaction emanated entirely from Dr. Cronin's own spontaneous and momentary reflection; and, so far from being approved, met with my decided opposition. Neither was it Dr. Cronin's object to infer from the decomposition, that the poison would have become inert; but that the colour, from the formation of Prussian blue, would have been so completely different from that of her former medicine, that her distrust would have been *efficiently* excited. Dr. Cronin acted entirely upon his own responsibility; and so far from the suggestion being made use of in any part of the defence, the only further allusion, was Mr. Bell and Mr. Morson expressing *merely their doubt*, not any absolute certainty, that no such reaction would ensue; with which view, I believe, Dr. Scoffern concurred. The writer, I presume, has satisfied himself upon the reaction between black oxide of iron and prussic acid. I considered the matter of so little importance that I have not examined the subject, but this I may say, that there is high authority against the conclusions of the writer.

There are some other obscure insinuations which are sufficiently discreditable to the writer, to justify passing them over in silence. But the conduct imputed to me by the writer, and transcribed into your pages, fully warrants me in claiming a place in your journal for this explanation.

ROBERT VENABLES.

5, St. Vincent-place, City-road, April 12.

VAPOUR OF ETHER IN SURGICAL OPERATIONS.

CASE OF MRS. PARKINSON.

[To the Editor of the Medical Times.]

SIR,—Having well considered this case, so far as the materials I now possess will enable me to do, I shall be obliged by your allowing me an opportunity of making a few remarks—promising that I wish only to deal with the case in reference to the experiment with the vapour of ether, not desiring to give any opinion as to the medical or surgical treatment of the patient in other respects.

In the first place, the patient was not in a state favourable to the experiment. "She was a delicate woman, subject to cold on the slightest occasion." (Evidence of Mrs. Leake). "She was very much out of health, and was directed to wear the child; and leeches were repeatedly applied to the tumour, at intervals of two or three days. The operation of acupuncture was repeated several times. Mr. Robbs had tried the effect of the administration of the vapour of ether twice before, and failed in producing complete insensibility." (See Mr. Robbs's own statement in the *Medical Gazette* of the 2nd.)

2. Another unfavourable circumstance in the case was the fact of the operator having no faith in the experiment, having only been induced to try it by the solicitation of the patient.

3d. The apparatus (a) employed was not properly constructed: the air-valve being closed by a poised weight, instead of being open to admit the free ingress of atmospheric air. Under such arrangement, the patient becoming insensible, and, especially in a protracted operation, would not probably inspire with sufficient force

(a) I have been favoured by the editor of the *Times* with a sketch of the apparatus used—a copy of which I will endeavour to forward to you in a day or two. This and a reference to the replies to my former queries will make these remarks more clear.

to admit the air. This would present a serious check to the experiment. The valve of expiration, being closed by a poised or kind of flute-key stopper, would not act so freely as that which I have been in the habit of using—a conical one. This would have a tendency to cause the patient to inspire and expire again into the same vessel, thereby vitiating the ethereal vapour, and subjecting the patient to asphyxia. No provision was made in the apparatus to generate a little aqueous vapour to be mingled with the ethereal vapour and atmospheric air, which would render the ethereal vapour less irritating to the lungs; nor had it the power to purify impure ether; nor was there any stop-cock, or any other contrivance, for regulating the admission of the vapour.

4. The patient never appears to have been completely insensible, nor were proper precautions taken to adjust the mouthpiece, so as to enable the patient to inhale the vapour in sufficient volume and density to render the nervous system insusceptible, nor was the vapour administered continuously. "During this period she cried out much, complained, and writhed in great pain. It was suggested by all present, to be advisable to re-administer the vapour, as its proper effects were not produced. I consequently requested Mr. Dillbin and my son to replace the inhaler to the patient's mouth, while I continued my dissection. The inhalation was not continued during the whole of the time, nor was it re-applied till the cries and struggles of the patient became so great as to be under no control; and then, both Mr. Dillbin and my son state that it was very imperfect and only at intervals, the position of the patient being very unfavourable." (Mr. Hobbs's own statement, see *Medical Gazette*, April 2.) It is also stated that the conjunctiva was sensible.

5. The specific gravity of the ether, when perfectly pure and free from acid or alcohol, is 730. In this case it is stated to have been 733 t, 765.

6. The parties who administered do not appear to have had much experience in cases of importance; six or seven times—several cases being merely extraction of teeth, and one the removal of a portion of a toe. No case of importance is mentioned in which they have previously tried the experiment.

7. The mouth and nostrils were not properly closed, so as to exclude atmospheric air during the second inhalation. The position of the patient was very unfavourable. (See Mr. Hobbs's statement.)

8. The apparatus in this case was placed below the mouth, and the ether, being heavier than atmospheric air, does not so readily ascend without some little effort on the part of the person inhaling it. Operators should bear in mind, that ether vapour is very heavy, having a specific gravity, at a temperature of 60° and a pressure of 30 inches, of 2.58 to 1 compared with air; owing to this, it falls to the bottom of vessels, and may be poured from one vessel to another much more readily than carbonic acid; hence it follows that, when the apparatus is above the level of the patient's mouth, the respiration of the vapour is much facilitated by its density and its tendency to flow at once into the lungs; the reverse happens when the source of the ether vapour is below the level of the patient's mouth.

9. The appearances of the body are not such as would justify the expression of an opinion, that death was caused by the ether, especially with the limited experience at present possessed.

"The lungs were pervious, they were a little congested at the posterior part, which witness attributed to the position at the time of dissolution. The heart was healthy in structure, but more flabby or flaccid than usual, and containing rather less blood than usual. The brain was quite healthy, with the exception of the upper part of the anterior lobes, the membranas of which were congested with blood, and there was no effusion in the ventricles."—(Evidence of Mr. Eaton.)

Amussat states that "The anatomical altera-

tions observed in animals killed by the inhalation of ether were distention of the heart from accumulation of dark blood in all its cavities; congestion of the lungs, liver, and kidneys; the brain betraying signs of hyperæmia in some cases."

Had the medical gentlemen ever been before engaged in, or present at, a *post-mortem* examination in a case of poisoning by ether?

Apologizing for the length of these remarks,

I remain, Sir, your obedient servant,

A. FAIRBROTHER,

Senior Physician to the Bristol General Hospital.
Bristol, April 12.

ON THE WORD CHEMIST.

By Dr. ADAM FERGUSON.

[To the Editor of the Medical Times.]

I have often asked myself the question, why it was that the dispensers of medicines and vendors of drugs called themselves chemists; and lately, on attending Dr. Cronin's trial, this question presented itself to me with redoubled force, inasmuch as the first vendor of drugs there examined admitted his almost total ignorance of chemistry—an ignorance which he owned was participated in by the majority of his class.

Now, as those who do not know chemistry call themselves chemists, *locus a non lucendo*, it is high time, I humbly opine, that those who do know chemistry should adopt some other name. I would propose, then, that they be denominated "Astronomers."

If you think my suggestion valuable, may I ask the favour of its insertion?

I enclose my card and address.

April 12.

PARTIAL ETHERIZATION.

[To the Editor of the Medical Times.]

Manchester, April 12.

SIR,—Will you be so kind as to insert the following remarks by way of appendix to the paper which you did me the favour to insert in the last number of the *Medical Times*?

At page 132 I stated as my last proposition—"That an operation should never be undertaken when the patient is only partially etherized and still capable of feeling acute pain; as in such condition, with many patients, the pain, emotion, and shock to the nervous system are likely to be greater than if they were in the natural state." In confirmation of this I beg to quote the remarks of M. Roux, at page 137 of your last number:—

"M. Roux stated that complete insensibility was far preferable to the second period of the effects of ether, during which irritability had on various occasions been evidently increased."

At page 632 of the last number of the *Medical Gazette* we have another instance recorded of the sudden death of a patient operated on under the partial influence of the ether. Mr. Eastment says—"As soon as the patient was brought under its influence, which was the case in about three or four minutes, Mr. Newman operated with his usual skill and judgment (it was for a compound fracture of the left thigh, with great laceration of the soft parts); but the patient's suffragings, on making the circular incision, were so severe that the intelligent and humane clergyman of the parish, Mr. Martin, who personally waited on the boy throughout the operation, remarked that the remedy was quite a failure. The inhalation was now employed the second time for two or three minutes, and with decided benefit, as far as the entire suspension of suffering was involved; another operation (in which the loss of blood was most trifling) was concluded. With its conclusion our difficulties and anxiety commenced, for our patient was in such a state of exhaustion and apparent intoxication that we soon considered his life to be in danger; and our fears were but too fully realized, for, in defiance of all the watchful attention it was in our power to pay, he sank in less than three hours after the

operation. The state of the brain during this period was peculiarly distressing. There were alternate manifestations of excitement and depression of the sensorial powers; at one time resembling delirium, at another, like approaching syncope, and again, like violent intoxication; and these alternate conditions continued until the poor boy died." And Mr. Eastment further adds—"On a review of the above case, I am not only induced to consider that the inhalation of ether partially failed in suspending pain, but I also attribute the death of the patient to its narcotizing effects on a nervous system previously depressed by great and extensive injuries." The patient was only eleven years of age, and had sustained simple fracture of the right thigh, in addition to the injury of the left, which had rendered amputation necessary. I have quoted the case so fully, as being a good illustration of the propriety of the proposition which I have quoted above from my former paper, as to the caution which is requisite to be observed, to guard against operating on patients when only partially etherized.

The last case of amputation of the humerus, referred to in my last paper, I have the gratification to say has gone on in the most satisfactory manner. The patient not only suffered nothing during the operation, but there was far less hemorrhage than is usual in such cases; and the system was so tranquilized that she never required an opiate, and has assured many professional gentlemen, who have since seen her, that she has suffered more pain from a cut finger than from the breast since the operation. The reaction was just sufficient to aid the adhesion of the divided parts by the first intention. The pulse was only ninety the second day, eighty the third, and seventy-eight the fourth, and since then has never been more than seventy-two. Amongst others who visited this patient, and expressed their gratification with the results of the case, Dr. Knox, the experienced and talented editor of the *Medical Times*, honoured me by accompanying me to see her dressed on the twelfth day after the operation. The dressing used for this, as well as the former case, was water-dressing, with spongio-piline: no plaster was ever applied. The stitches were all removed by the sixth day, by which time the adhesion was so complete as to require no application of plaster.

I forgot to add, in my last communication, a most important fact in proof of hypnotism being less objectionable, in a moral point of view, than ethereal narcotism, which is this—that the same patient, who manifested the most intense erotic indications during ethereal narcotism, has been frequently hypnotized by me without the slightest indication of the sort being ever manifested by her during the sleep.

It is worthy of being recorded, that I have found ethereal narcotism of the greatest benefit for suspending the intense pain of dysmenorrhœa. I know it has been recorded as having been tried with considerable success in several other painful affections, but I am not aware of having seen any account of its application in the above-named most painful affection; however, the success which has attended its use in my own practice, in most intense cases of the sort, warrants me in submitting the fact to the consideration of my professional brethren.

I have the honour to remain, Sir, your most obedient servant,

JAMES DRAID, M.R.C.S.E. &c.

THE POSITION OF THE APOTHECARY.

[To the Editor of the Medical Times.]

SIR,—Your well-known impartiality to the different branches of the medical profession induces me to expect your insertion of the following remarks, concerning the supposed right of the Apothecaries' Company to legalize their members to act as general practitioners. In the reign of James I., the apothecaries and grocers were incorporated into a company; but, shortly afterwards, the apothecaries obtained a charter for

themselves, and by degrees got into the habit of prescribing medicines without having recourse to the physicians; and, as Pope, in his "Essay on Criticism," has it—

"So modern 'pothecaries, taught the art,
By doctors' bills, to play the doctor's part,
Bold in the practice of mistaken rules,
Prescribe, apply, and call their masters fools."

This innovation was exclaimed against as an infringement on the privileges of the physicians; but the apothecaries seem to have kept possession of the new ground they had taken up, and the Act of 1816 has placed them on a sound footing as *apothecaries*. But, with all their authority, I submit they have no claim or title whatever to assume the position of general practitioners, whose province it is to act both as surgeons and apothecaries. The knowledge of surgery is not expected by the examiners at the Hall: their regulations make no mention of this needful qualification to the general practitioner; and yet we are informed in your journal, a few weeks ago, by the deputation to Sir G. Grey, *they*, the apothecaries, are the only legal general practitioners. Many students content themselves with passing the Hall, and assume the title of surgeons, without either surgical practice, lectures, or examination; but a member of the College, whose curriculum of study embraces every requirement of the Hall, save medical jurisprudence (vide *Medical Times Almanack* for 1846), and passes an examination on those points, which are of the most importance to a general practitioner, is to be considered an improper person to practise as such. Truly a conclusion like this is above my comprehension, and, if an explanation could be given by the said deputation, it would oblige many surgeons, as well as your subscriber and well-wisher,

CHIRURGES.

Derby, March, 1847.

MANCHESTER EYE INFIRMARY.

[To the Editor of the Medical Times.]

SIR,—You have already received exuberant information from numerous correspondents on the "use and abuse" of ether. But you have not, I think, had much evidence of its employment in "ophthalmic surgery."

On Thursday last Mr. Walker operated at the Eye Institution of this town on two cases of cataract. In one patient he operated on both, in the other only on one eye (the right), a very low degree of vision being possessed by the left, sufficient for the present to postpone the interference of the knife and its possible consequences. It is a very judicious rule not to recommend an operation so long as the patient has sufficient sight to enable him to find his way about. Of course, cases where the patient himself, from circumstances, desires the operation, form the exceptions. In the first case ether was administered by means of Robinson's or Hooper's inhaler. The patient was not rendered so insentient as not to reply when spoken to, and during the operations there was the outward indication of pain or feeling manifested by a slight contortion of the muscles of the face; restrained respiration, the apparently suppressed exclamation of suffering, together with a general tremor of the body; yet, when the operations on both eyes were concluded, in answer to the interrogatories put to him by Dr. Robinson, "Did you feel pain?" he replied, "No."—"Will you now undergo the operation?" "Oh, yes, I am quite ready." On being told that all was over, he exclaimed in gratitude, "Bless the Lord! bless the Lord!" To the spectators this seemed to be a very unsatisfactory and imperfect experiment; but, if the patient's apparently guiltless statements are to be depended upon, the condition induced was quite perfect enough to render him insensible to the pain; more than that was not needed. My own opinion on this particular case is not yet formed; as to many of the cases, of triflingly painful operations, in which ether has been used, I have thought that some error as to its effects might arise from those singular stoical persuasions and resolves which have

been very ingeniously set forth in this journal, and in another department of medical philosophy by Mr. Braid of this town.

In the operation for cataract ether is not likely to be found serviceable. In the case referred to it was disadvantageous by producing so much upturning of the eye, and consequent interference with the pupil, as to make the lower section of the cornea a necessity. And this seems to be the usual concomitant or result of its employment. The relaxation of one set of muscles, which permits a contraction of the other set which induces this state, also gives a tendency to draw the eye backwards and upwards into the orbit, rendering the naturally sunken eye more so, and vastly increasing the difficulty of the operation. These circumstances, together with the consideration that the operation, whether viewed abstractedly or comparatively, is attended by little pain—the cornea seeming to possess a low degree of sensibility—will militate against the use and value of this valuable surgical boon. In the extirpation of tumours from the vicinity of the orbit, and in the removal of the eye itself, it will prove equally serviceable.

In the second patient the ether was not used. On being questioned as to the painfulness of the operation, he replied, "Oh, it was nothing particular."

Mr. Walker expressed his determination not to use it again for cataract. I have only to add, at this time, that having now witnessed many of this gentleman's operations, I am persuaded that his double-edged cataract knife (a drawing of which was given, *Medical Times*, Vol. XII., p. 107) seldom fails to make a sufficiently free incision for the escape of the lens—a circumstance upon which the success of the operation chiefly depends. I have never seen it fail in his hands.

A medical gentleman from Ashton was present, who stated that he had never failed to produce the full effects of ether by causing the patient to inspire it from the internal surface of the spongio-piline cloth fitted to the mouth.

A. W. CLOSE.

Grosvenor-street, Manchester, March 22.

A FACT.

SIR,—The marked difference that there is between the diploma of the Royal College of Surgeons in London, and that of the members of the Royal College of Surgeons of England, has not been, as far as I have observed, publicly noticed. Yet the difference appears to me to be a serious one, as it places the members of the new college in a class inferior to that to which the members of the old institution belong. The new diploma informs all men that A. B. has been examined and found to be a proper person to be admitted a member. The old diploma has the following important clause, "AND AUTHORIZE HIM TO PRACTISE THE SAID ART AND SCIENCE ACCORDINGLY." The reformed college, perhaps being quite sure that Sir James Graham's bill would pass, and that, as the license to practise would then issue from the board that would be formed in virtue of the act, it would be superfluous for the college to give to the new members their license; but no such bill has passed, nor can any one tell when it will pass; in the interim these members are left in the lurch. In fact the new diplomas are certificates of competence and of membership; but are, properly so called, no diplomas at all. Surely the surgical under-graduates would be justified in demanding from the college a license to practise, put down in black and white, that they might show to all men that they have an authority to practise surgery. The College of Physicians and the Court of Examiners of the Society of Apothecaries give licenses; why, then, has the College of Surgeons ceased to do the same?

I would like to see what defence this line of conduct will fairly admit of. I confess I can only look upon it with disapprobation.

I am, Sir, your obedient servant,
London, April 7. CANDIDUS.

COMMENTS AND SUGGESTIONS UPON THE SUBJECT OF MEDICAL REFORM, And the Measures hitherto proposed for the future Regulation of the Medical Profession.

The subject of Medical Reform has been one so long contemplated and called for; and one that has hitherto met with so little success or unanimity of opinion, that the author of the following observations is induced to lay them before the professional public with the hope that, if the subject is again brought before the attention of Parliament, more efficient measures may be sanctioned than any hitherto proposed, and with the firm belief that they are only open to severe comment from the unqualified part of the profession.

Public exposure has proved useless in at all counteracting the progress of quackery; nor has any efficient measure been suggested to restrict the daily innovations upon the profession, or the assumption of the title of M.D. or Dr. by persons wholly unentitled to it, or to suppress the fulsome and obscene quack advertisements which disgrace so many of the metropolitan publications, and almost every provincial newspaper.

One proposition before the public at present is, that upon an annual registration, every practitioner shall pay a fee of "five shillings." Now, it is suggested, by a comparison with the legal profession, that a much larger sum, for an annual certificate, should be paid—viz., in the following ratio: that gentlemen registering and practising as physicians, and pure surgeons, should pay for the first three years of entering into practice, five guineas for an annual certificate, and for each subsequent year, eight guineas; and that the sum of three guineas for the first three years, and five guineas each successive year, should be paid by the "general practitioner." That many exemptions must be allowed as regards the medical officers in the different services, the stipendiary officers of eleemosynary institutions, assistants, and others, is evident, although their exemption would prove no obstacle to their due registration. As a counterbalancing advantage for such an oppressive sum, as many may at first proclaim that proposed for the annual certificate, the total of which, it is suggested, should become part of the revenue, it must be borne in mind, the Government, in consideration of that amount, should undertake to enforce summary measures to prohibit all future sale of quack medicines, and also by similar measures suppress the practice of all other than duly qualified and, by virtue of such qualification, annually certificated practitioners. Thus a source of revenue would be collected from the profession itself, to compensate the loss sustained by the Government by the suppressed sale of quack medicines; and the qualified part of the profession would hardly deem such measures oppressive, if they were strictly enforced, and if the half and wholly unqualified practitioners were restricted from practising, which too many do, to the bane of the public both in London and the provinces, and to the unjust prejudice of those who have devoted their time, talents, and finance in completing the required course of education according to the protracted course of study required by the educational institutions (a).

A summary mode of penalties for the suppression of empirical and unqualified practitioners must meet with the general approval of at least the qualified part of the profession, should such ever be carried into effect, and also the future enforcement of a general uniformity in

(a) "The London Medical Directory" for the present year returns a list of upwards of 300 parties practising as general practitioners who have returned no qualification at all, and more than 180 who publicly acknowledge the possession of but one diploma, and that of a much more recent date than 1814. Those so practising in the country would doubtless form a formidable addition to the half and wholly unqualified list.

the course of study on the part of all future candidates for admission into the profession; and, for the furtherance of that desirable object, the same period of time should be imposed on each future student, and a precisely similar routine of attendance on lectures, and at the hospitals, whether in London, Dublin, or Edinburgh. Notwithstanding the distinction between medicine and surgery is so generally admitted to be merely nominal, yet, on the principle of the division of labour, and from the general attainment now so much demanded, a second or medical examination should be enforced at each of the above-named cities, *in lieu of that of the Apothecaries' Company*, and a certificate of such examination, and the diploma from one of the Royal Colleges of Surgeons should be enforced, as *the legal standard of qualification*, from every practitioner of medicine and surgery in the kingdom. Some gentlemen have agitated the subject of instituting a college of their own; but the majority who have become members of either of the Colleges of Surgeons would be found far from desirous to resign the privileges—limited as they are—which, by their examinations and acknowledgment as members of the same, they have become entitled to. Far from wishing the total abolition of the examination at the Apothecaries' Society, it is submitted that a knowledge of "pharmaceutical chemistry," "materia medica," pharmacy, and even botany, ought to be demanded from the chemist and druggist, to whom is intrusted the preparation of many important prescriptions, and who, at the present time, sell too indiscriminately many deleterious and dangerous articles; and were the due examination of the chemist and druggist, and a more strict regulation of the sale of the powerful medicinal poisons, and a *standard national rule for the manufacture* of them, intrusted only to the Society of Apothecaries, it would be found that inquests would be less frequent upon children, "Poisoned by laudanum," "Godfrey's Cordial," &c. Arsenic for rats would be less heard of; mistakes of oxalic acid for Epsom salts, and reversed labels, would less frequently occur, and innumerable other errors of omission and commission, by which—it is a too fatal truth—many a valuable life has been sacrificed, an invalid state of health continued, and other evil consequences, aggravating the "ills that flesh is heir to," when not actually fatal. The prohibition of a diversity of formulae for the manufacture of the same preparation is urgently required—an existing evil, in great measure, auxiliary to the present painful position of Dr. Cronin, as regards the difference of strength in the different formulae for making laurel-water; and, if the errors of our neighbours may make us wise ourselves, the death of many fellow-creatures at Paris, in 1830, by the mistaken use of the "acide cyanhydrique hydratique" for the "acide cyanhydrique medicinale," should surely demand the enforcement of every precaution that the Legislature and professional prudence can suggest.

That an efficient registration of every qualified member of the profession is very desirable must be obvious; but it appears questionable whether it would not be more effectually promoted and effected if it were under the direction of a presiding medical council, having a board in London, with a principal officer of state as the President, as suggested in the former bill of Sir James Graham: such a board or council, being formed of one or more of the eminent physicians, surgeons, and general practitioners of London, Dublin, and Edinburgh; and forming at once a court of appeal and redress for any attack on a practitioner's professional reputation; and to be invested with the power of discontinuing the annual certificate or privilege to practise, upon any due and efficient proof of wilful malpractice, negligence, or ignorance of any party hitherto qualified, or even the degrading use of *hazard-bills*, which some are mean enough to circulate—in the same manner as a disreputable member of the law is struck off the rolls. Such a presiding board would also prove an

effectual source by which might be enforced statistical accounts from different parts of the kingdom, the presidencies, and the British settlements, and also for the due investigation of the causes, effects, treatment, &c., on the appearance, or during the prevalence, of any epidemic.

Another object might also be thus attained, viz., a due investigation of the actual merits and efficacy of any new mode of treatment, as instanced by the novel application of etheral-vapour inhalation, at present undergoing uncertain investigation at the various public hospitals. That agent's safety should be sufficiently tested and approved of, before dabbled with by incompetent parties, or used in private practice, for the extraction of every decayed tooth, that is much better removed without it.

Any new drug, or combination of drugs, worthy of being added to the "Pharmacopœia" or "Materia Medica," might be similarly ordered by such a board to have an efficient trial and investigation, by the medical officers of the public institutions, prior to an unlimited use, or sale among the public. It cannot be imagined that the tenor of these remarks at all imply the prohibition of the sale of a box of pills or any other simple remedy by the dispensing chemist, although they aim at the suppression of the sale of quack medicines, with the precise composition of which the medical profession are in ignorance.

Is it not an anomaly that, in the profession of the law, should any innovator dare to undertake the management or direction of the legal affairs of society, he is immediately punished both by fine and indictment, and that the lives and health of the public may be placed in jeopardy by any *et-dévant* mechanic like St. John Long, or any impostor possessing "impudence" as his only qualification? Surely magisterial power should in future have a right of interference: for the author can authenticate instances in the north of England where "bone-setters"—a class, it is to be lamented, not yet extinct—have caused irremediable mischief in mere cases of simple dislocation. The parties applying to such impostors err from that degree of ignorance which renders them the more entitled to protection from the law, and an efficient suppression of such dangerous practice.

It is not intended here to comment at any length on the physician's department of the profession, further than to observe the title of Dr. or M.D. should verify to the public all that is implied by it—but which is far from a reality at present—viz., a higher degree of attainment, both in general, educational, and professional proficiency; and to ensure which, the Continental, Glasgow, and Aberdeen degrees should be abolished; and those of London, Edinburgh, and Dublin should be in strict conformity with each other in the amount of attainment required from the candidates for so high a professional position, by a preliminary university education, and, subsequently, a lengthened period of study at the metropolitan and continental hospitals. The degree of M.D. also should be attainable as an honorary distinction to the accomplished practitioner, as the council might think proper to bestow it, and to others, as at present, as licentiates, by examination after a fixed period of honourable practice and consequent experience. London, March 20.

GOSSIP OF THE WEEK.

QUEEN'S COLLEGE, BIRMINGHAM. The first sessional examination of the students in the department of general literature and science took place on Saturday the 10th and Monday the 12th inst., when the following list was returned by the examiners:—*Classics.* 1st Class: Fryer, Coleford; Wall, Stratford-on-Avon; Yarwood, Birmingham; Edney, Craig Kilmarnock. 2nd Class: Seven.—*Mathematics.* 1st Class: Wall, Fryer, Yarwood. 2nd Class: Edney; Rice, Stratford-on-Avon; Rose, Madeley; Wilkinson, Northleach, and A. T. Davies, Birmingham,

equal. 3rd Class: Three.—*Chemistry.* 1st Class: Edney, Fryer, Wall. 2nd Class: Five.—*Examiners:* Lyttelton, M.A.; James T. Law, M.A.; W. M. Lawson, M.A.; George Richards, B.A.; John Taylor, B.A.; George Shaw; E. W. Day, M.R.C.S.

ROYAL COLLEGE OF SURGEONS.—At a meeting of the Court of Examiners on Monday, the 12th inst., the following gentlemen, having undergone the necessary examinations for the diploma of this College, were admitted members, viz.,

Chelsea; George B. Barron, Southport, Lancashire; Frederic Robinson, London; James Henry Richardson, Toronto, Upper Canada; Oliver Pemberton, Birmingham; Frederick Acret, Toronto, Upper Canada; Edwin Cotton Cottingham, London; and Richard James Hansard, London.

ROYAL COLLEGE OF SURGEONS.—Gentlemen admitted members, Friday, April 9:—E. P. Wilkins, E. Lund, C. J. Gibb, R. J. Brackley, C. Mackenzie, W. E. Hayman, R. B. Painter, J. H. Prosser, and W. B. Gill.

EDUCATION, SCIENCE, AND ART.—The Miscellaneous Service Estimates (No. 4) contain an account of the sums proposed to be appropriated during the current financial year to the purposes above mentioned. The sum total which the Government will require from the House of Commons amounts to £349,043, against £325,908 in 1846, and £300,218 in 1845. The sum total will be thus distributed—viz., £100,000 for public education in Great Britain, and £100,000 for the same purpose in Ireland; £6500 for Schools of Design, £2006 for the University Professors, £4536 for the University of London, £7480 for the Scotch Universities, £300 for the Royal Irish Academy, £300 for the Royal Ulster Academy, £6000 for the Royal Dublin Society, £2600 for the Belfast Academical Institute, £18,518 for the British Museum establishment, £47,959 for the British Museum buildings, and £3152 for purchases; £5537 for the National Gallery, £8961 for the Museum of Practical Geology and Geological Survey, £4094 for scientific works and experiments, and £2000 for the completion of the monument erected to the memory of the late Viscount Nelson.

FRENCH JUSTICE.—The Parisian courts have just punished by fine and three months' imprisonment a keeper who, having to watch a suicidal patient, fell asleep and gave the latter an opportunity, which he used, of self-destruction. It appeared in evidence that the keeper had used all kinds of stimulants to resist sleep with no effect.

A Dr. Outman, of Washington, wishing to test a magnetic somnambulist, suddenly applied to her nostrils a bottle containing cayenne pepper. The doctor suffered instantly a severe scratching in the face from the fair subject, and subsequently a legal process, in which he was condemned to pay less than one farthing damages.

It has been ascertained that the rate of mortality is considerably higher among the medical students than any other class of students in the French capital. From 1825 to 1846 inclusively, thirty-three medical students died from dissection wounds alone.

The greatest astonishment has been excited among the Turks by some successful surgical operations which have lately been performed at Constantinople upon patients under the influence of ether.

The following is a copy of a "General Order" regarding "relative rank" in the medical department, recently issued to the American navy by the late chief of its executive, Mr. Bancroft:—

"Surgeons of the fleet, and surgeons of more than twelve years, will rank with commanders."

"Surgeons of less than twelve years with lieutenants."

"Passed assistant-surgeons next after lieutenants."

"Assistant-surgeons not passed next after masters."

Commanding and executive officers, of what every grade, when on duty, will take precedence of all medical officers.

"This order confers no authority to exercise military command, and no additional right to quarters."

The above important order, so gratifying to the medical body in the United States navy, has been obtained through the instrumentality of Dr. William Maxwell Wood, now surgeon of the fleet in the Pacific, who has also been the means of obtaining many other gratifying orders tending to improve the condition and standing of the medical gentlemen employed in the American service.

The students of the faculty of medicine in University College are about to present to Dr. Taylor, late Professor of Clinical Medicine, a testimonial expressive of their estimation of his character and talents.

POISONING BY CANTHARIDES. The following French case is curious from the repeated attempts made to destroy life. The accused was a man, aged forty-one years, a carpenter by trade, and of an appearance, gestures, and conversation nearly verging to idiotism. His attempts were made on a step-brother, named Hervonet:—During May, 1816, Hervonet, shortly after eating some soup, which tasted extremely bitter, was seized with violent pain in the stomach and bowels; he could not pass urine but with extreme pain, and the quantity discharged was small and bloody. After suffering several hours, he was enabled to sleep, and, on waking, found himself much better. He had no suspicion of the cause of this illness, but during the night of the 5th he was seized with similar symptoms. Two hours previous he had eaten soup of similar bitterness to the last. This time his sufferings were more severe and longer continued, and they only yielded after copious draughts of oil and sweet milk, which excited copious vomiting. Even yet he had no idea of any intent at poisoning. On the evening of the 12th of July he found in his soup a black substance, which at first he supposed to be fragments of vegetables. A portion of this adhered to his palate; he detached it with his finger and examined it by the light, but could discover nothing certain, except that the taste was precisely similar to that experienced in the two previous instances. The next morning he was impressed with the idea that it was cantharides; and all doubt was removed on showing it to M. Drew, a medical man, who also informed him that two days previous he had seen his step-brother purchasing medicines from an apothecary. Hervonet denounced his brother to the authorities; and, as soon as Poirier heard of the charge, he fled, but was soon retaken. He confessed that he had purchased a blistering plaster on the 10th of July, and mentioned where he had hid it. On obtaining it all the plaster was found scraped off. It was also proved that he had made several purchases of the same nature; and an apothecary deposed that one of the plasters sold contained two grammes of cantharides. The character of Poirier was proved to be extremely bad—a thief, of idle, looting habits, and a burden to his relatives. His father, aged eighty, had given his property to his son-in-law and daughter, leaving Poirier only an allowance. The jury found him guilty, and he was condemned to death; but scarcely had sentence been pronounced before eleven of the jurymen united in a petition for a commutation of punishment. His apparent idiocy seems to have been the ground for this. —*Gazette des Tribunaux.*

TOPICAL APPLICATION OF SULPHATE OF QUININE.—Dr. Wedderburn, of New Orleans, extols ("New Orleans Medical and Surgical Journal," January and September, 1816) the efficacy of the sulphate of quinine in the treatment of indolent ulcers. He applies it in solution, ten grains to the ounce of water. In a subsequent number (November) of the same journal, Dr. Richard Lee Fearn, of Mobile, states that during the last five years he has frequently treated chronic conjunctivitis, and urethritis, by direct applications of quinine dissolved in distilled water. In the latter cases, believing that the inflammation usually existed to the bladder, he has directed the injection to be thrown into it. He further says that for ten or twelve years he has treated chronic ulcers, especially those resulting from burns, with a preparation of quinine, prepared chalk, and powdered rhubarb, with marked benefit.

CARRAGHEEN MOSS.—Dr. Frank, of Wolfenbuttel, employs a compound powder of Irish moss as an article of diet for phthisical patients, and for children affected with tubercles mesenterica. It is prepared as follows, and has a most agreeable taste:—Take of Carragheen moss, cleaned, 3ss; spring water, 3xvi; boil down to one half; strain with expression; and add to it strained liquor, white sugar, 3iv; gum arabic, in powder, 3i; and powdered orris-root, 3ss; heat to dryness with a gentle temperature, stirring constantly, so as to obtain a pulverulent mass, to which three ounces of arrowroot are to be added with trituration. A jelly is prepared with this powder, by rubbing up a teaspoonful of it with a little cold water, and then pouring a cupful of boiling water. —*Journ. de Chemie Med.*, Sept., 1845.

DISSECTION OF THE MAN MONKEY.—We have already stated that Hervio Nano bequeathed his remains to an eminent surgeon for dissection. The *Literary Gazette* gives the following account of the construction and appearance of the body:—"This extraordinary cripple exhibits the very rare combination of perfect symmetry, strength, and beauty, with a great amount of deformity. The head is remarkably fine in form, and the expression intelligent and benign; the chest, shoulders, and arms form a perfect model of strength and beauty; the arms are exceedingly muscular, and the hands very well and strongly formed; when standing, the arms could reach the ground easily, so as to be employed in progression or leaping; in the place of legs, there are two limbs, the left about eighteen inches from the hip to the point of the toes, the right about twenty-four from the same points. The feet are natural. The easiest mode of explaining the nature of these limbs is to say, that it seems as though the thigh-bones and muscles had disappeared, and the knee-joints beel raised up to the hips; the bone on the one side is tolerably like a leg-bone, on the other it is compressed into an immensely strong bone of triangular form, with the base upwards, and knitted to the hip with very strong ligaments. These limbs are furnished with the muscles which should have belonged to the thigh, and those of the leg are much increased in size; the muscles of the calf being comparatively small, on account probably of his mode of walking, contribute to give the limb the look of a lion's fore-arm. Nearly double power must have been obtained over the feet by this arrangement; and this would account for his extraordinary feats of leaping, such as following a horse at full speed on the hands and feet, and suddenly springing on its back like a monkey, or jumping ten feet in the air. His mode of fighting, too, was most original; he used to spring in the air, and at the same instant deal the most terrific blow upon his unwary antagonist's head, so that he was a very formidable combatant. It is said that in his palmy days, while driving his cab, a clumsy carrier drove against him, and, as usual, accused Hervio of being in fault, at which our hero sprang from his seat on to the back of the man, and gave him a most terrible thrashing. His feats of strength in his monkey characters are well known. A very good cast of the entire figure has been made which will doubtless be shown to those who may be curious in such matters."

The number of persons, says the *Temperance Gazette*, who drink to intoxication, in England alone, is not less than one million!

OBITUARY.—On Tuesday week, at Burton, in Kent, Westmoreland, aged 69, John Armstrong, Esq., on Feb. 20, at Cahir, of fever, Michael Daniel, Esq., Surgeon to the Fever Hospital and Dispensary.—Feb. 28, of fever,

David Smith, M.D., Medical Assistant of the Middleton Fever Hospital and Dispensary.—Lately, at the Grange, Melton, aged 70, Thomas Bland, M.D., a magistrate of the county of Suffolk.—On the 28th of December last, at Minritius, where he had gone for the benefit of his health, J. F. Waller, Esq., M.D., of the island of Antigua, and late of 28, New Bridge-street, aged 39.—On the 16th ult., at Southampton, at the early age of 28, Julius Veronge, Esq., M.D., Surgeon of the Royal West India Mail packet Dec.—March 19, Dr. A. McLachlan, of Oban, Scotland.—March 6, at Limerick, Dr. Murdin, 55th Regiment.—March 20, at Newcastle, H. T. Brummell, Esq., Surgeon.—On the 26th ult., at his residence, in Bedford-square, Thomas Wilkinson King, Esq., of Guy's Hospital, Surgeon.—At Milnthorpe, on the 23rd ult., Dr. Porteous, Surgeon, R.N.—At St. Alban's, on the 30th ult., aged 63, universally esteemed and regretted, John Coates, Esq., Surgeon, one of the magistrates of that borough.—At Tripoli, February 27, John Dickson, Esq., M.D., Surgeon, on the half-pay of the British navy. Dr. Dickson had been resident at Tripoli upwards of thirty years, and such had been the extent of his gratuitous attendance on the indigent, that his decease was looked upon as a great public calamity. His funeral was escorted by a military guard of honour, sent by the Pacha, and attended by the Foreign consuls, by all the European residents of every class, and by several thousands of Jews and Mahomedans.—March 16, at Southampton, aged 28, Julius Veronge, Esq., M.D., Surgeon of one of the Royal West India Mail packets.—March 20, aged 71, Charles Rechement Aikin, Esq., of Bloomsbury-square, a member of the Royal College of Surgeons, and well known for his scientific and practical knowledge of chemistry.—March 26, in Bedford-square, T. Wilkinson King, Esq., Surgeon, Lecturer on Pathological Anatomy, &c., at Guy's Hospital.—On the 11th of January, killed in an encounter with the Caffres, while on detachment from the camp, on the Koe River, Caffreland, Frederick Howell, Esq., Assistant-Surgeon of her Majesty's Rifle Brigade, son of T. Jones Howell, Esq., of Priuknash-park, Gloucestershire.

MORTALITY TABLE.

For the Week ending Saturday, April 10, 1847.

Causes of Death.	Total.	Average of 5 Winters.
ALL CAUSES.....	1051	914
SPECIFIED CAUSES...	1049	900
Zymotic (or Epidemic, Endemic, and Contagious) Diseases.....	174	106
SPORADIC DISEASES.		
Dropsy, Cancer, and other Diseases of uncertain or variable Seat.....	98	99
Diseases of the Brain, Spinal Marrow, Nerves, and Senses.....	171	158
Diseases of the Lungs, and of the other Organs of Respiration.....	314	275
Diseases of the Heart and Blood-vessels.....	47	26
Diseases of the Stomach, Liver, and other organs of Digestion.....	87	70
Diseases of the Kidneys, &c. Childbirth, Diseases of the Uterus, &c.	13	8
Rheumatism, Diseases of the Bones, Joints, &c. ...	16	8
Diseases of the Skin, Cellular Tissue, &c.	4	2
Old Age.....	64	57
Violence, Privation, Cold, and Intemperance.....	25	28

No. 895.

LECTURES ON SURGERY,

SAMUEL COOPER, Esq., F.R.S.,

Professor of Surgery to University College, London
Consulting Surgeon to London University Hospital, &c.

LECTURE II.

It is necessary, gentlemen, that I should recommend to you those works which may serve as text-books to you in your studies. The only book in which true surgery can be learned is the book of Nature; this is always correct. Entire confidence cannot be placed in any written works or lectures, however great may be the science of the writer or lecturer. Each of you must study the diseases and injuries of the human body for yourself, in the wards of our hospital. You will there gain that experience which I dwell upon in my introductory lecture, and be enabled to compare the lesson you have received, and the information contained in books, with the diseases and injuries themselves.

As any single individual, however diligent, would be unable to gather all the valuable information now in existence by his sole experience, even by the most assiduous attendance on a large hospital during the whole of his professional life; it becomes necessary to examine what the experience of previous observers have accumulated for our instruction. Books have been the means by which this vast storehouse of experience has been raised, and it is from them that you will derive great assistance in perfecting your professional education.

The works on surgery may be divided into two classes—manuals and treatises. The former are intended to place before the student the outlines; the latter to give him an extended view of the science. Information has also been thrown into the alphabetical form of dictionaries, for greater convenience of reference. In the First Lines of the Practice of Surgery, which I have written as an elementary work for students, you will find the outlines of surgery treated in a clear and distinct manner, and adapted for the initiation of the student into the first principles of the science. Although I may run the danger of appearing to boast of my own performances, I shall recommend this work to you for careful perusal; and I am justified in doing so by the approbation of the profession, as shown in the extensive sale of this manual. I cannot too highly estimate the excellent work of

my colleague, Mr. Liston, on Operative Surgery, or impress upon you the necessity of an attentive examination of its valuable contents. As a larger work, and one especially designed for reference, you will find "The Dictionary of Surgery" I have written a valuable addition to your library, containing as it does, perhaps, the largest accumulation of the opinions and practice of modern surgeons in existence.

In addition to these works, I must advise you to dip, as much as your time will permit, into the works of earlier observers, of whom I may mention Hunter, Thompson, Sir Astley Cooper, and Lawrence, among our own countrymen; and Dupuytren, Velpeau, and others, among our continental neighbours.

I would further strenuously advise you to peruse the accounts of cases published in the transactions of societies, and medical journals, as they give you a more definite view of the circumstances which arise during the progress of cases which could not be conveniently introduced into general treatises.

Some preliminary matters must be explained before I can enter upon the particular departments of surgery. These general remarks are equally applicable to medicine and surgery, and will be treated of by the professor of medicine in a more extended manner than myself; but still I am compelled to go over the same ground in a more cursory manner, in order to facilitate the comprehension of the doctrines of surgery.

All diseases and injuries of the human body are usually distributed into three great classes: *physical, organic, and functional.*

Physical injuries and diseases arise from mechanical causes. Most of these are caused by external bodies, but some depend on the abnormal actions of parts within the body. Among the former are wounds produced by cutting, piercing, or contusing weapons; fractures from blows, falls, or the forcible elongation of the bones; dislocations produced by violence of some kind; hernia or protrusions of the bowels by the forcible compression of the diaphragm and abdominal muscles, and deficiency in resistance of the abdominal walls. Some of these injuries may be produced by violent actions of the body itself, without the interference of an external agent. Thus, fractures may be produced by violent muscular contractions, or the muscles or their tendons may be lacerated from the same cause; but it is truly of little importance whether the cause of these injuries be external or internal: the effect remains the same.

The lodgement of extraneous bodies within the body is another form of mechanical or physical injury. It is of no great importance whether these are introduced from without, or formed within the organs by the agency of chemical or physical laws. Their presence in either case produces mechanical irritation and functional disturbance of the parts.

These physical injuries are not vital pheno-

mena, since we can produce them with equal facility in the dead subject. They may be said to be generally produced independently of life; the vital operations originating subsequently, for the reparation of the injury sustained by the parts.

Organic diseases consist in changes of the natural structures of organs, or in the production of new substances or tissues bearing no resemblance to the natural texture of the parts; or being in some respects analogous to other tissues or organs. By the expression *organic disease*, we generally understand, in this country, all diseases of structure; but some of our continental neighbours limit the term to those diseases alone in which the normal structure altogether disappears, and is substituted by new and different tissues.

Mere alterations in colour, size, density, and arrangement of tissues are not sufficient, in the opinion of all pathologists, to constitute an organic disease. The changes in structure which constitute organic disease are dependent on the perverted action of the capillary vessels, whose office it is to form the tissues; but we are entirely ignorant why one rather than another of these changes should be produced. We are in the dark as to why tubercle, encephaloid, cancer, or melanosis, should be formed, rather than some other modification of organic disease.

From the nature of organic disease, as I have now explained it, you will readily perceive that one great character of it is its incurability whenever it attacks a vital organ, or the circumstances are such that it cannot be removed by the knife.

Organic disease may either exist in an organ without total destruction of its natural tissues, as when scirrhus is produced in the cellular tissue of the mamma, leaving portions of the gland in a natural state; where it is an adventitious production, entirely independent of the gland; or it may attack the gland itself, which is then completely changed in its nature, and is converted into the tissue of cancer. A more correct explanation of this change would perhaps be, that the deposition of the cancerous structure, and its pressure on the tissue of the gland, had caused the absorption of the natural tissue.

Functional diseases differ from organic, in being attended by no perceptible change in the tissues of the organ: they are simply those that depend on imperfect or irregular performance of one or more of the functions which, in a healthy condition of the body, are performed with freedom and ease. It is true that there is no *visible* change in the size, texture, or position of the organ whose functions are impeded; but we may infer that wherever there is functional disease there is an accompanying change in the structure of the organ, although we are unable to discover its nature.

Every part or organ has its own peculiar duty

to perform; but the performance of this duty is not solely dependent on itself, but partially on other organs with which it is mutually connected. All the organs of our body are thus connected, and sympathize with each other: so that injury or disease of one organ puts the whole machine out of order. If it were not so, one organ might perish without injury to the whole body. Hence, in consequence of this mutual connection of all the organs, the function of each organ must be studied in reference to the whole system of organs in the animal economy.

Certain diseases, then, may arise which are not dependent on injury or disease of the particular organ in which the disease is manifested, but depend on affection of some remote organ. Amaurosis, or loss of sensibility of the nerves, occasionally arises from worms in the alimentary canal, or some other gastric disorder, and is removed by treatment directed to those particular states. Convulsions, as is well known, often depend on intestinal irritation, worms, or tension of the gums. Syncope may be produced by powerful odours. These are examples of functional diseases. As these diseases are dependent on mere derangement of function, or, at most, on some trivial change of the organs, they are for the most part as curable as the organic diseases are incurable.

The causes of disease are usually arranged into *proximate* and *remote*, and remote causes are divided into *predisposing* and *exciting*. The proximate cause of disease has given rise to much discussion; but, after all that has been written on the subject, it really signifies not the cause of the disease, but the changes in the system which constitute the disease. As is often the case, want of precision of meaning may be observed in terms which are in daily use in the profession. It is not uncommon to hear the assemblage of symptoms which show the presence of disease confounded with the diseased action, so that we may take the proximate cause as signifying the state of the system which gives rise to the symptoms.

The true causes of disease are the predisposing and exciting. Predisposing causes are those which place the body in such a condition as to render the person liable to disease on the application of the exciting cause; and the term may be applied with equal correctness to previous states of the system of the individual which act in the same manner.

Certain of these predisposing causes are general, affecting a large number of persons at the same time: as sometimes occurs to all the inhabitants of a large town, city, or empire; to a large body of men crowded together in barracks or hospitals, and preparing the way for diseases of a similar or analogous nature in the individuals attacked.

Peculiarities of parentage, sex, constitution, habits, profession, age, and condition in life are individual predisposing causes. The transmission of disease from parent to child has been a fruitful source of dispute: because healthy parents have often brought forth unhealthy children, while diseased parents have, on the other hand, produced healthy children. Yet there can be no rational doubt that predisposition to particular diseases is transmitted in this way, although a part, or even the whole, of the progeny may escape the disease peculiar to the family. In the majority of cases, however, the rule holds good that predisposition to disease or constitutional peculiarity is transmitted by descent. Sometimes these hereditary diseases disappear in one generation to reappear in the next. Some diseases—scrofula, phthisis, gout, stone, and deformities—are notoriously frequent in particular families.

The different stages of life, childhood, youth, manhood, and old age, act as predisposing causes to particular diseases. Disease may appear at any period of life, from the earliest infancy to extreme old age; but each age has its disposition to certain diseases which are sometimes almost confined to particular periods of life, or show themselves more frequently in these than other

stages of existence. Thus congenital hernia, spina bifida, navi, or harelip accompany the child into the world. Until the seventh year, children are more liable to rickets, croup, scrofula, prolapsus of the rectum, worms, incontinence of urine, porrigo, and other affections connected with dentition. About the period of puberty we observe inflammations of the chest, phthisis, hæmoptysis; and in females all the disorders that accompany the commencement of menstruation. Middle age is characterized by tendency to abdominal affections: hæmorrhoids, cancer, and other organic diseases, make their appearance. In old age, apoplexy, palsy, ramollissement of the brain, mental decay, calculus, deafness, cataract, sphæculus, prostatic disease, and other affections of the urinary passages.

Sex predisposes to peculiar diseases, partly dependent on the diversity of organs of the two sexes, and partly on the difference of general habit of body. Both sexes are liable to most diseases; but, from difference of habits and occupations, men are more exposed to wounds and fractures, contusions and dislocations; from the length and narrowness of the urinary passage, stone in the bladder and retention of urine are much more frequent; they suffer more, also, from rheumatism and gout. Cancer, bronchocele, and an infinity of nervous disorders are more common among women. Inguinal hernia occur most frequently with men, while women are more commonly the subjects of umbilical and femoral hernia. Those diseases which affect the organs of generation are, as a matter of course, peculiar to the sex; thus, men suffer from hydrocele, sarcocele, varicocele, and orchitis; while cancer, prolapsus uteri, diseases of the breast, ovarian dropsy, and others, belong exclusively to the females.

The structure, uses, and situation of individual parts of the body exert an influence as predisposing causes. The lower extremities are thus much more subject to varicose veins, ulcers, and fractures, than the upper. The imperfect ossification of the bones of children permits the separation of the epiphyses—an accident which could not occur in adult age. Weakness of certain parts of the abdominal walls gives a tendency to hernia. Cancer frequently commences in the skin, mucous membranes, and glandular structures. Caries attacks the short and spongy, while necrosis makes its appearance in the long and solid, bones.

The distended or empty state of the hollow organs, as the bowels and bladder, makes a great difference in the chance of laceration of these organs. Falls or blows, when the bladder is much distended, are apt to burst that organ, as you see in these specimens of laceration of the bladder taken from our museum. Such lacerations of the bladder are inevitably followed by fatal peritonitis, gangrene, and death, produced by the effusion of urine into the cavity of the peritoneum.

Trades and professions exercise considerable influence on the health of parties who follow them. Coachmen, postillions, and others, who almost live on horseback, very commonly present themselves with aneurism of the popliteal artery, hernia, and diseases of the testicle. Those whose occupation keeps them in a standing position are very liable to varicose veins and ulcers of the legs. Chimney-sweepers, again, are almost the only persons attacked with cancer of the scrotum, which here is produced by the constant irritation arising from accumulation of soot in its rugæ. Painters are liable to a peculiar kind of colic, induced by the absorption of lead into the system, and to paralysis of the hands, arising from the same cause. Sedentary occupations induce disorders of the digestive system, obstinate constipation, hæmorrhoids, apoplexy, and various nervous affections.

Station of life, again, exercises a powerful influence on disease. The difference of habits, of diet, and even of education, will account for the differences of disease with which each class is affected. Wounds, sprains, dislocations, frac-

tures, scrofula, itch, and other cutaneous diseases, are proportionally more frequent among the poorer classes. Although the poor suffer much from rheumatism, they escape gout—the disease of the rich, indolent, and highly-fed classes of society.

Prognosis, although it sometimes depends on the progress of disease, as exemplified in phthisis, often predisposes to other affections, such as hæmorrhoids and varicose veins. It has been stated that fractures do not unite well during this state, but I once attended a woman who broke her leg while pregnant, in whom the bones united as usual, in five or six weeks. Improperly, excess or deficiency of food, insufficient clothing, and intemperance, are powerful predisposing causes of disease. I might enlarge much on these matters, and show the effect of overfeeding, sloth, and consequent plethora, in producing inflammatory affections; but I must now pass on to the examination of existing causes, which are divided into *common* and *specific*. The common exciting causes of disease may be either diffused through the atmosphere, applied to the surface of the body, or, again, introduced into the cavities or tissues. The discussion of those states of the atmosphere which produce disease is rather medical than surgical, and belongs more properly to a course of lectures on medicine. The causes immediately applied to the body are abundant in surgery. Such are the causes of wounds, stabs, lacerations, or gunshot injuries; all derangements of texture, situation, or figure of organs produced by violence; inflammation, ulceration, and mortification, produced by pressure, and also the action of chemical substances on the body. The venomous bites of serpents and other animals, in which, at the same time the wound is given by the tooth, a venomous matter is introduced into it. Disease, again, may be induced by substances introduced into the cavities of the body, as in cases of poisoning, foreign bodies lodged under the eyelids, in the auditory passage, larynx, or œsophagus.

The retention of matters which are naturally expelled from the body is another source of disease. Retention of urine sometimes produces paralysis, inflammation or rupture of the bladder. Retention of fecal matters in the colon and rectum may give rise to fever, inflammation, distention, vomiting, and other unpleasant effects. Retention of the menstrual secretion in the uterus causes painful distention of that organ, and great disturbance of the general health.

One disease is not unfrequently the exciting cause of another. Ruptures and wounds of the stomach, intestines, and bladder, permit their contents to flow into the general cavity of the abdomen, and excite fatal inflammation of the peritoneum. The presence of an aneurism may cause absorption of bone, atrophy, and disorganization of muscles, obliteration of large veins, and change of structure in nerves. Strong muscular exertion often gives rise to hernia, prolapsus uteri, and even rupture of blood-vessels. Emphysema of the lungs may be produced in like manner by rupture of the cells of that organ. Occasionally the violent and irregular action of a muscle will tear some of its own fibres, rupture tendons, or even fracture bones.

A COURSE OF LECTURES ON CLINICAL MEDICINE,

Delivered in the Theatre of Queen's College, Birmingham.

By SAMUEL WRIGHT, M.D.,

Physician to Queen's Hospital, and Professor of Clinical Medicine in Queen's College, Birmingham; Physician to the General Dispensary; Extraordinary Member, and formerly Senior President, of the Royal Medical, Royal Physical, Hunterian Medical, and Cuvierian Natural History Societies of Edinburgh, &c.

Recapitulation of the leading facts concerning the fever of 1846; type of acute diseases varying with locality and state of health of the individuals attacked; illustrations; effects of bad air in acute diseases; summary of the process of respiration; Blackhole at Calcutta; another case in our own country; minor examples; deleterious effects of

constantly breathing an impure air:

of the typhoid type would be the probable one; were he simply in a state of debility, without his system being depraved, at the period of seizure, nervous fever would be pretty sure to be his.

of deleterious effects upon the living system; examples; value of personal and domestic cleanliness both in health and disease.

GENTLEMEN,—I have now said all I have to say, in detail, concerning the typhoid fever of 1846, as it affected this town and neighbourhood; but before dismissing the subject, let me call your attention to a few general facts bearing upon it, which appear to me to be worthy of consideration.

I have already told you that this fever seemed to be little affected by, or dependent for its rise and ravages upon, local circumstances. Two of the worst cases of it which I saw were, respectively, in William street, near the Five ways, and in Frederick street, Harper's-hill—situations as elevated, open, well ventilated, and drained, as most in Birmingham. Though the lower parts of the town suffered severely, and perhaps more so than those better situated, yet the latter were not exempt from the visitations of the malarial, which seemed to have little choice in its progress, and to find a locality and a victim indiscriminately and anywhere.

This peculiar feature in the origin and spread of the fever I speak of—a feature I never witnessed in any epidemic or endemic disease before—I can only account for by supposing that its advent and extension were due to some general cause or causes—atmospheric or telluric, or both. This seems to me to be the only opinion consistent with the history and particular manifestations of the ailment; and it further harmonizes with a probable explanation of certain phenomena for which both the animal and vegetable world were remarkable during the summer and autumn of last year.

My object in recapitulating this part of a subject upon which I have already dwelt more fully than I had intended is, lest what I have stated as a curious exception in the natural history of fever and of most acute ailments should by any of you be construed into a rule. The rule in the general spread of maladies is, that they will most incline to, and most devastate, the low, damp, dirty situations where poverty and wretchedness reside. I am the more desirous not to be misunderstood upon this subject because it is one to which I have for some years past paid considerable attention—one which I think it imperatively concerns every medical practitioner to make a part of his every-day study, and one which each of you will, or at least ought, hereafter to regard with an anxious interest. Moreover, it is intimately related to the great question of health of towns, which, as you know, is now prominently before the Legislature and the public, with every probability (so let us hope) of being determined consistently with the purposes of civilization and science.

Acute diseases, with very rare exceptions, as I have told you, either suffer an aggravation or derive some particular type according to the situations where they may prevail, and the previous health of the individuals whom they may attack. Of fever, for example, we have a great many varieties, but it is probable that they are all reducible to a single radical whose variations are the offspring of contingencies of person or locality. Thus, a robust individual, inhabiting a healthy elevated district, if attacked with fever, would probably exhibit this in its simplest type; if he lived in an open marshy situation, it would be likely to appear in an *intermittent* form; if this situation were in a hot country, in a *remittent* form; had he just arrived, or been long a resident, or his health previously shaken in any way, the function of the liver would contribute a character to the general ailment, which might thus occur as *yellow fever*; were his digestive organs in a state of derangement at the time of the advent of the fever, this would be likely to appear as the variety called *gastric*; were he in indigent circumstances, and the inhabitant of a low, damp, ill-ventilated

Of the many circumstances which contribute to retard the progress of cure in acute diseases, or to change the character of them, bad air and uncleanness are perhaps the most prominent. The respiratory function, you know, is of cardinal importance in maintaining the health and strength of the living frame. If this function be impaired, either from defect in the apparatus performing it, or from the medium of respiration being insufficiently pure, debility and disease follow as a matter of course. To give you, summarily, an idea of the importance of the respiratory process, and of the requirements thereof, it has been ingeniously calculated, that in every twenty-four hours' breathing, by a man of average age and stature, twenty-four hogheads of blood are acted upon by fifty-seven hogheads of air—upwards of eleven hogheads of oxygen being converted into carbonic acid. This is supposing the atmosphere required to be of a healthy quality. If this ratio be deviated from, *ceteris paribus*, the living system suffers proportionately. If the supply of air be considerably less than that needed, suffocation sooner or later occurs. The history of the catastrophe at the Blackhole of Calcutta, in 1786, is a pitiable illustration in point. Into this den, eighteen feet square, and furnished with two small windows on the same side, one hundred and forty-six Englishmen were thrust! Most of them became apoplectic in about four hours; at the end of six hours, ninety-five were dead; in the morning but twenty-three were found alive; and of this trifling number the majority subsequently died of typhus, engendered by the filthy corrupt air they had breathed.

Later, and in the more civilized country which ourselves inhabit, a miniature example of this ignorance and barbarism occurred. A set of drunken constables, according to Walpole, amused themselves by capturing all comers in their way, and depositing them in St. Martin's roundhouse. About five-and-twenty persons were thus disposed of for the night, in a small apartment that was denied ventilation either by door or window. The next morning four were found dead; two died shortly afterwards; and twelve were severe sufferers long subsequently.

Respiration, you know, not only takes away the oxygen of the atmosphere, but supplies its place by a corresponding quantity of carbonic acid. Whenever this reaches 10 per cent., the air becomes absolutely unfit to breathe. In such a medium an individual would shortly suffocate. It was thus that death was produced in the instances I have quoted. A milder deterioration, but still a mischievous one, occurs whenever crowds of people meet together, in ordinary, in a space too limited, or ill ventilated. Most of you must remember the oppressive headache, the languor, and stupidity that have followed a long incarceration in a crowded public room, the doors and windows of which (as is customary in these cases) were closely shut. And some of you, I have no doubt, have curiously remarked, on occasions like these, how dimly the lamps burnt at the close of the evening in comparison with their brilliancy at its commencement. Carbonic acid, the produce of respiration, added to exhalation from the surface of the body, was the cause of all this. Now, you can easily imagine, from a knowledge of the effects thus suddenly produced by confinement in impure air, how mischievous must be the constant respiration of an atmosphere below the standard of wholesomeness. It is not possible, but that deteriorated health, or disease, must result from it. Let me give you an example or two.

It was stated at the Medical Section of the British Association in 1834, by the registrar of the Lying-in Hospital of Dublin, that in 1781, every sixth child died within nine days after birth of convulsions; and that, after complete

ventilation had been secured, the mortality of the infants in the five following years was reduced to one in twenty.

In the second volume* of the Poor-law Reports, it appears that in 1836-37, some important disclosures were made concerning the deteriorated health of children in large day-schools. In one case, after the establishment of suitable ventilation, not less than 1100 children were kept in constant good health, where previously 700 were weakly or sickly.

In Glasgow there is attached to one of the factories an assemblage of buildings for the work-people, called, from its construction, "the barracks." Some time ago this place contained 500 persons; every room contained a family. This crowded state, and the consequent deterioration of the atmosphere, were productive of a typhoid form of fever, of which, in fact, the place was never entirely free. Still the deluded people could not be persuaded to open their doors and windows to secure ventilation. At last, however, they were prevailed upon to allow a tin tube of two inches diameter to be fixed into the ceiling of each room. These several tubes communicated with a general one, and this with the chimney of the factory furnace. In this manner a constant current of air was secured, and the result was, that during the ensuing eight years fever was scarcely known in the place.

One cause of the unhealthiness of Liverpool, in comparison with most other large towns, is the impure air which many of its inhabitants breathe, owing to the small space allotted to each individual. Its condition at this moment, as you know, is frightful from this cause; but, even with its average number of inhabitants, its provisions for the entertainment of the poorer of them are very wretched. At a round guess, every individual vitiated, or renders unfit for respiration, in the course of a night, 300 cubic feet of atmospheric air; yet it is not uncommon in the cellars in Liverpool to find thirty people huddled together in an apartment whose contents, in cubic feet, are only 2000! Can we wonder that, in places like these, fever, in its worst forms, thus the wretched inhabitants? In the best-regulated prisons 1000 cubic feet are allowed to each prisoner, not less than this being considered necessary to the maintenance of his health and strength. In a confined court, in Crossie-street, Liverpool, two or three years ago, there were 118 people living on an area of 150 square yards—about one square yard and a quarter to each! At the time I speak of, fifty cases of fever (nearly one half the inhabitants), besides other ailments, were attended in this place by the dispensary. Liverpool, as you know, is one of the unhealthiest towns in the kingdom, and Birmingham one of the most salubrious; for this difference many reasons are to be assigned, but certainly one of the chief of them is the fact that, in the former place, there are 100,000 inhabitants to the square mile, and in the latter only 33,000.

The history of the hospitals of this kingdom is full of instructive truths that relate to this important subject. Numberless are the instances in which fever has been the issue of crowding patients too closely. An eminent surgeon, the late Mr. Pearson, when attached to the Lock Hospital, London, uniformly observed that fever prevailed in the establishment when more than a certain number of patients were placed in any of the wards. Repeated observations of this kind induced him afterwards to limit the number of beds in each ward, and the consequence was, a complete absence of fever from the place.

It has frequently occurred to me, in the discharge of my dispensary duties, to remark how much more common, and more difficult of cure, is fever in the lower and more confined parts of the town, than in those better situated. Many times, when the opportunity has been afforded me of having a patient removed from the one site to the other, this has been done, and very little further treatment has then been necessary. This not only applies to fever patients, but to

others suffering from various affections, both acute and chronic. And old dispensary patient of mine inhabits a small house in Bromsgrove-street, and, assisted by her daughter, keeps a day school. I have seen in her room, certainly not more than twelve feet square, upwards of thirty little urchins perched together. The odour has often been stifling at the moment of entry. The old lady, unlike her daughter, takes little or no exercise out of school hours, and is therefore subject to frequent attacks of dyspepsia. In many of these I have attended her, and, contrary to the general rule of practice, have always been most successful when keeping her in bed—that is, keeping her in a better atmosphere than that of the crowded schoolroom.

You remember what a severe accession of febrile symptoms, with hæmoptysis, the consumptive patient Clays had in the hospital, when two extra patients were added to the small ward he tenanted; and how much he rallied when removed into another room that was better ventilated. Jones, again, the boy with *diabetes mellitus*, had progressed satisfactorily for eight weeks in the top front ward; but, in consequence of the demands upon our space, we were compelled to put three more beds into that room; and the resulting vitiation of the air so affected the lad that he has never rallied since.

Even the inferior animals suffer to a great extent from being confined in impure air. Anatomically, there is no appreciable difference between a tame rabbit and a wild one; but physiologically, the difference is very remarkable. All this depends upon the relative air they breathe. Let the former be turned into an open country, and he will soon acquire fleetness and florid muscles, and lose all the characteristics of confinement; let the latter be pent up in a noisome atmosphere, and his eye will become languid and watery, his muscles flabby and pale, and his abdomen tumid; if he do not speedily die, he will degenerate and become scrofulous. I have never yet met with evidence of tuberculose in a wild rabbit; and I have seldom seen a tame one without it. Cows that are closely confined in ill-ventilated places frequently die consumptive. Those belonging to the milkmen of Paris used to be thus destroyed in great numbers. Since their habitations have been made larger and more lofty, the mortality has proportionately decreased. Horses suffer less from the limitation of their stables, because they are generally out of them in the daytime; but the discovery was not long ago made, that some of the cavalry barracks in this kingdom were too small and too imperfectly ventilated for the number of horses kept in them; and thus was a strange mortality amongst the horses accounted for. It is said that by an improved mode of ventilation of the barracks at the "Polytechnic" saving of several thousand pounds only has been effected.

When the sphere becomes rendered impure by the exhalations of decomposing animal or vegetable matters, it is absolutely unfit for the purposes of respiration. It becomes deadly, in fact, in proportion to the faint it may have received. The instant emanation of death being instantly produced by exposure to certain effluvia of decomposition. Nightmen have often thus fallen victims to their unenviable calling. Not many years ago, twenty-three children belonging to a boarding-school at Clapham were simultaneously attacked with excessive vomiting and purging, convulsions, and prostration of strength. Two of them died in twenty-four hours. These sufferings arose from the poor children having been exposed to the effluvia of the contents of a cesspit which had been emptied into their play-ground. It is calculated that in the island of St. Kitts, east out of every ten children, between one and two die of their exposure to the effluvia of the cesspit. The only explanation of the prodigious mortality rests with the filth and the impure air; and the noxious effluvia that pervade the houses, the floors of which they generally contrive to cover, during the winter, to the depth

of several feet with accumulated stores of manure.

When the exhalations of decomposition are not potent enough to produce death in a direct manner, they may yet produce it indirectly by generating disease, or by encouraging the generation of it. It is thus that fevers spontaneously arise, and that epidemic diseases find a "local habitation and a name." When the cholera was prevalent at Nottingham it was confined to a few streets, and those the lowest, least ventilated, and most filthy in the town. The better parts were untouched by the malady. In the village of Bulwell (where I was born), four miles from Nottingham, the cholera raged awfully over a certain spot of ground. This melancholy spot, one hundred yards long by fifty broad, lost one hundred and twenty residents in less than a month! The tenements were small, ill-ventilated, and damp, and there was scarcely one that had not its own manure-heap before its own door.

The village of Basford, two miles nearer Nottingham, suffered almost as severely in those parts of it that were exposed to the filthy exhalations from open sewers, pigsties and other accumulations of dirt and decomposition. The village of Hyson Green, a mile still nearer Nottingham, scarcely registered a case of cholera. It is situated higher than the other two, has a more permeable soil, and its inhabitants are, for the most part, cleanly in their persons and homes.

Fever, of the typhoid type, is the most common consequence of exposure to the noxious exhalations of dying or dead bodies. The "Black Assize" at Oxford, in 1577, is a sad illustration in proof. The lord chief baron, the sheriff, and about 300 others, who were in court, were infected by the stench from the prisoners (most of whom were in a horrible condition), and the majority died within forty hours, of a disease resembling typhus. The Old Bailey session of May, 1750, is memorable from the fact, that most of those who sat on a particular side of the court (the lord mayor, two judges, and an alderman, were amongst the number) breathed the emanations from the bodies of the filthy prisoners, and most of them fell victims to typhus.

Wherever the effluvia of decomposition are abundant, there also will fever of the typhoid or typhus variety be a likely resident. Those of you who have visited patients in the Jukleys, in Park-street, John-street, and other localities of this town, in which ventilation and drainage and domestic cleanliness are not conspicuous, can subscribe to the truth of what I say. Even in a situation otherwise healthy, the temporary deposit of filth has often a very marked effect. I was attending a patient for simple fever in a comparatively healthy part of Birmingham. Just as he was verging upon convalescence, a quantity of animal manure of an offensive kind was deposited in a yard close under his bedroom window. In less than twenty-four hours he was the subject of typhus. You remember a similar case under my care at the hospital acquiring a typhoid character directly that the next bed to hers became tenanted by a patient with a large sloughing offensive sore.

Did time permit, gentlemen, I could add to these examples very many more. It is not necessary, however, that I should do so, for you must understand the motive with which I have detailed those already given. They carry their own comment. My wish is to convince you how necessary to the maintenance of health, and to the recovery of it, are cleanliness and pure air.

CLINICAL OBSERVATIONS ON SOME OF THE MORE FREQUENT DISEASES OF CHILDREN.

By W. HUGHES WILSHIRE, M.D. (Edin.), M.B.S., Lecturer on the Royal Infirmary for Children, &c. &c.

(Continued from p. 128.)
GENTLEMEN, Having said thus much, generally, on the subject of scrofula, I shall now draw

your attention more particularly to the nature and character of those morbid actions which are usually considered as scrofulous diseases. You will remember that I stated, that before a person can be said to labour under such affections, he must evince a morbid action going on in his body, either to be reckoned as a form or degree of inflammation and its results, such as exudation, suppuration, or ulceration, or else as a form of true tuberculous disorder. I also remarked, you will recollect, that he may in many cases exhibit the twofold signs of this important malady, scrofula. For the sake of clearness, and what I consider of practical utility, I shall draw a line between these two great forms or exemplifications of scrofula, although, as you now know, there exist practitioners who believe that the peculiar deposit called *tubercle* is *always* present somewhere or other in that body which is yielding to the ravages of the great disorder.

It may be very true that both in the *lymphatic glands* and *bones*, and even in *fusus*, a deposit of a peculiar character—by some thought to be exactly analogous to true tubercle, by others called "scrofulous," "cheesy," or "lardaceous matter," and supposed to be somewhat different from it—takes place, sometimes before, sometimes after, inflammation has existed; yet I am equally certain that inflammation of a scrofulous character may go on in these and other structures, and yet not be either preceded or followed by "tuberculous," "lardaceous," or cheesy deposit. Now, without referring to the marks of scrofulous inflammation as it evinces itself in any special form of malady, I shall give you its general characters, deduced from several. You will find, however, that scrofulous inflammation and its results present the same characters, in most respects, wherever they may happen to be seated, although, of course, they are particularly easily recognizable when they are seated near the superficial parts of the body; for here you can follow their whole course and progress, and you will soon discover how this specific form of inflammation is to be known from that which is generally understood by common, healthy, or phlegmianous inflammation, from rheumatic and gouty, erythematic and syphilitic, states of hyperæmia.

Now, I will just call to your mind the great signs of inflammation, as given amongst the aphorisms of the schools—*heat, swelling, redness, and pain*. Of course you know as well as I do, that, in many healthy or common forms of inflammation, one or other of these signs may be wanting; but in the scrofulous inflammation, marked alterations of every one generally exist. Of course it is in inflammation of the surfaces that these signs of healthy inflammation are best seen; and it necessarily follows that we best find these variations in scrofulous inflammations when it occurs in like situations. The more acute the common inflammation, the greater are the heat, the redness, and the pain; the more chronic, as a general rule, these things are less forcible. Now, scrofulous inflammation is generally of a subacute character, or often chronic, and very slow in its progress to any given result. It is true, we may have it of a pretty acute character; but the general rule is, mind, it is not so rapid in its progress, is less active in all respects, than inflammation of another form; and, further still, is far less amenable to the usual forms of treatment. As you would expect, then, the heat and pain are not so considerable, and change of colour does not so readily or early occur, as in other cases; and, when the latter ensues, it is not of the bright red arterial hue generally observed: it is often of a dusky venous hue, sometimes even livid. With regard to the *swelling*, however, that is very different: it is constantly greater than in common healthy inflammation; and, what is more, the bulk of the part often becomes materially increased in size before the patient complains of anything else; and, even then, he often only complains of this from the mere mechanical inconvenience. When a gland is affected, it often becomes enormous, swollen, and even of a stony hardness; and thus will

remain for a long time—the surface quite void of inflammatory colour, and no appreciable heat present. What is worthy of notice is, also, that in certain cases, where great increase of bulk takes place in an organ, there does not appear to be that hindrance to the performance of function which you might have expected would result. In many of these cases, also, you have the greatest difficulty either to retard or to forward any future progress: they remain as sluggish as ever, in spite of all you can do.

Although there is this sluggishness of action about scrofulous inflammation, yet, expose a scrofulous person to the common exciting causes of this morbid action of the capillaries, and he more readily yields to them than another constitution does—sluggish as the result truly is, and of course varying in degree according to the tissue or organ which may happen to be attacked.

When suppuration ensues, the pus does not readily and quickly make its way to the surface; and when it does, you do not find it pointing in that manner which you see in common inflammation: the skin, however, becomes much disorganized and detached, and yet only a small opening allows the pus its exit. Often, again, the matter formed never comes to the surface at all by its own free will, as it were, but burrows down and around, often making its way into very important cavities and structures; or, on the converse, it may make its way at the surface by several narrow fistulous openings, formed for the purpose, or the result of old scrofulous sores. There is another point, in connection with suppuration, I must speak of, which is, that the matter which forms, and the discharge which results, differ from like points observed in common inflammation. Of course they will vary according to the degree of acuteness or sluggishness of the inflammatory action: the more chronic this is, the more will they differ from those of the common form. In point of consistency, the effusion will vary from thin serum to that of concrete pus: the former may be seen coming from a chronically inflamed gland; the latter observed in the meninges at the base of the brain, in certain very important affections of children. I do not pretend to enter upon the chemical and microscopic differences of the scrofulous discharge and effusions seen to exist, from those observed in other instances: you will find plenty of information on this point in the various late work on animal chemistry; but I must inform you, nevertheless, that I believe no specific composition can be assigned to them, nor any constant, unvarying characteristics. Sometimes the discharge is very like common purulent matter, in which, however, the pus globules will become fewer and fewer, and the effusion gradually more and more watery; or in the transition you will find small thin flakes of aplastic albuminous material, or a curdy, cheesy, or lardaceous substance, or tuberculous matter. Let a scrofulous abscess be opened which has been attended with inflammatory action of acute character, and you may have very nearly *laudable* pus. This abscess, instead of filling up, will discharge a thin serous fluid, charged with albuminous flakes or curdy matter; but if the inflammatory action has been chronic, very sluggish from the beginning, the primary effusions at once partake of the latter character.

The ulceration which so generally succeeds to suppuration is, like the previous action, slow, sluggish, unquid, and inactive. The disposition to heal is but little, and constantly thwarted by the tendency to the formation of nasty fistulous sores. The very appearance of the "wound" is bad; it does not look as if it had the least intention of becoming healed; and thus it will often remain for a long while with a thin ichorous or sanious discharge. Sometimes, again, when a scrofulous ulcer heals, the surface of it at once betrays its unhealthy character, and it looks as if it was always ready—and it really is in many cases—to break out again on the supervention of the least amount of exciting cause. The skin retains an unhealthy redness or blueishness: it

looks as if it had been forcibly stretched over the surface of the sore and compelled to unite with it against its will; there is a puckering of it; a marking of its surface by radiating lines and striae, and in point of texture it looks weak and thin. Upon some slight disturbing cause, either locally or constitutionally applied, the cutaneous covering again ulcerates, and once more gives forth its thin unhealthy discharge. From this reiterated ulceration and peculiar puckering of the integument of the sores, when they do heal, you sometimes find the greatest deformity, especially when the face is the seat of the disease; and the deformity in extreme cases produces perfect hideousness of appearance. If you will take the trouble to refer to No. 388 of the *Medical Times*, you will find such a picture drawn by Dieffenbach that will make you shudder.

Now, gentlemen, from the insidious nature of scrofulous inflammation and effusion, it becomes very important that you should always be upon your guard when, in a suspicious-looking child, local indurations or enlargements are seen in or near important parts, such as about the neck, axilla, &c.; since the effusions may burrow amongst important vessels, or press upon the trachea, or do great mischief by infiltration into the cellular tissue. Sometimes very extensive chronic scrofulous inflammation of the cellular tissue, &c., exists, and only betrays its presence by the symptomatic irritation observed in the patient, which latter shows itself by fever of a peculiar form. Very often collections have taken place, and only been known after one-half of the effusion has been absorbed from its original place of deposit. In those cases, also, where we have abundant signs of what is going on, from the irritation upon the system induced by the very long-continued action of low scrofulous suppuration, from the absorption of effusions and formation of secondary deposits, from the inability of the assimilating powers to uphold the body during all this wear and tear, *hectic fever* is a common follower in the train. When the joints are involved, this symptomatic fever is seen to its full extent.

There is a very interesting point connected with scrofulous inflammation which I must draw your attention to; it is this—that it may exist to such an extent that its effects shall kill the patient, and yet you shall be scarcely able, from appreciable signs, to say for certain it is going on. This seems to be an extraordinary thing to say; it is true, notwithstanding. The only doubt I feel in saying this, arises from the debatable question, as to whether or not some kinds of effusion, the results of this inflammation, are or are not tuberculous; and hence the cases I allude to should more properly come under the other division which I made; however, I will refer to this point presently. Let me here tell you that inflammation may exist in a scrofulous child, invading the meningeal coverings of the brain, and in whom not a trace of tubercle or granule shall exist in the contents of the cranium. It is true, the readily-identified deposit shall exist in other organs, but not in the brain, and the patient shall die from their effects. In some of these cases, the symptoms of cerebral derangement during life are evident enough; but in others they are so "chronic" or "latent," and present symptoms so very variable and uncertain, that the attendant is surprised when the child suddenly goes off with "brain symptoms" of an acute character, or, on dying from an intercurrent malady, he finds the insidious mischief which has been taking place in the cranial cavity. Now, in very many cases of this peculiar form of meningeal disorder, undoubtedly, after death some tuberculous deposit is found in the brain or on its coverings, and you, perhaps, know how much we are indebted to Dr. Hennis Green for his researches into this peculiar "latent" form of tuberculous disorder. But in other cases we find only concrete pus effused, and no evidence of what I should call tubercle. If, of course, microscopists and chemists could make out this effusion to be tuberculous, these cases would be-

long to another form of scrofulous disorder; but this has not, to my mind, been done, and I believe them to be examples of scrofulous meningitis, without tuberculous deposit. I shall have, however, to refer again to this interesting subject when I talk to you about "hydrocephalus."

Again, primary chronic scrofulous inflammation may go on in the peritoneum without tuberculous deposit existing in the abdomen, although the latter exists in the lungs. At first the symptoms are often masked or latent, or attention is drawn to an intercurrent malady; but sooner or later the peritoneal affection will be apparent enough.

This scrofulous inflammation, of whose more general characters I have been speaking to you of, may occur almost anywhere, in some one or other of its forms, the skin, glands, and mucous membranes, however, are more frequently attacked by it; and hence you observe so frequently subacute and chronic inflammation of the cervical glands, eczematous affections, and inflammation of the edges of the eyelids, conjunctiva, lining membrane of the nose, and ear-passages, as well as of the organ of generation in the female child. It also attacks the cancellated structure, more particularly of the heads of the large bones, this being the first step in the progress of the affection, known by the name of *scrofulous disease of the joints*. It is not very apt to occur, however, in their shafts, and when it does it is always sooner or later accompanied by a yellow lardaceous deposit. But in all portions of the smaller bones, such as the phalangeal, metatarsal, and metacarpal ones, scrofulous inflammation will occur. It is seen also in the bones of the ear in bad cases of otitis. In some of these latter cases a true scrofulous caries results, and scrofulous necrosis may become engrafted upon the latter when it has attacked the more dense and compact portions of the skeleton. Of the frequency of the bodies of the vertebrae being attacked you are of course sufficiently aware. Articulating cartilage is liable to scrofulous inflammation, as a secondary disorder to the disease, first beginning in the cancellated tissue of the adjacent bone; but whether it is ever primarily attacked is a very doubtful point, and it is a point also too surgical for me to attempt to give an opinion upon.

The coverings of the brain, I have already told you, may be the seat of scrofulous inflammation, and this without necessarily being followed by the deposit of granulation of a tuberculous character; and it is probable that there are certain cases of white softening of the central portions of the cerebral substance itself, having scrofulous action as its main cause or foundation.

Whether the nerves themselves are ever subject to inflammation of truly scrofulous character, and in children, I am unable to tell you from any experience of my own; but I may remark that I have seen it stated in a German journal that *post-mortem* examinations of tuberculous subjects often show some abnormal appearance of the *sympathetic nerve*, although they may not have died really of the results of tubercle. Sometimes the nerve is found to be stiff and dry; in other cases, again, the ganglia are seen in a condition of gelatinous softening, or with a collection of reddish-coloured serum around the sheath. It has also been affirmed that the *cardiac plexus* has been found changed into hollow cells and tubes, surrounded by a red-coloured exudation.

When scrofulous disease attacks the lungs and air-passages, it is my opinion that it usually does so by first depositing tuberculous matter. Of course a morbid action of the vessels and circulating fluid must precede this deposit, both general and local in its character; but if this morbid action is not to be regarded as inflammation—and I believe in the greater number of cases it is not—why, then, we must regard the tuberculous deposit as the prime feature in the malady. But, notwithstanding this is the general rule, yet there does occur scrofulous inflammation of the lungs, and which may even kill

without there being a single tubercle deposited there. This inflammation may also occur primarily, and be rapidly followed by diffuse deposit of tuberculous matter; and this latter fact is by no means uncommon in children. In the scrofulous inflammation which attacks the lungs, and kills without tubercles being there, the deposit is different from that of common pneumonia: it answers all the same purposes as tubercle—it softens, breaks up, and gives rise to excavation. If I were to enlarge, however, upon this point, I should get beyond children as patients; as also, were I to talk to you of the inflammation of the upper air-passages which supervenes in adults upon the scrofulous disorder going on in the lower portions of the respiratory apparatus. You know, perhaps, that in children scrofulous disease of the latter does not usually go on to such an extent as it does in more aged persons. The scrofulous disorder of the lungs is more frequently complicated with other severe disorders, under which the child sinks before the mere lung affection proceeds itself to the extent necessary to kill; or the child dies, overwhelmed by the mass of malady its little frame is subjected to, no one single form of the disorder being actually the fatal one. It is well known to most medical men, now, that scrofulous inflammation often attacks the peritoneum, although it has been by some wrongly imagined that tuberculous deposits always accompany it. This is certainly not the case; however, it is frequently in children met with, in whom no tuberculous deposits exist, though it is very often an intercurrent affection of tuberculous disorder. This subacute or chronic peritonitis, it must be admitted, whenever it occurs, should always render us very suspicious of what may be going on in adjacent and other structures. The mesenteric glands are very liable to be attacked, either primarily or secondarily; and from the frequency of remittent fever in children of the scrofulous diathesis, in which disorder gastric intestinal inflammation is so usual a lesion, I am disposed to believe that the digestive mucous surface is specially amenable to inflammation of the character we are now discussing.

OBSERVATIONS ON THE ACTION OF MERCURY IN INFLAMMATION, AND ITS EFFECTS ON THE SYSTEM.

By HENRY SMITH, M.B.C.S.

Late House-Surgeon to King's College Hospital.

(Continued from page 133.)

Having endeavoured in my last paper to show that mercury acts in inflammation by producing a change in the quality of the blood, I shall now proceed to consider the injurious effects which it produces when it has been given with a view to alter the system; and I shall begin first with excessive salivation. We shall see that in this case the symptoms are almost entirely referable to absorption of a poison into the blood.

Now the effects of this powerful medicine are so well known, practitioners are more careful in its administration, and therefore seldom bring on that excessive state of salivation which was deemed to be necessary a few years ago. But, nevertheless, cases do occur where we have an opportunity of studying the bad effects of mercury, and every one who has seen much of hospital and dispensary practice has doubtless seen many severe cases of salivation and its concomitant evils; as that caution which is necessary in the taking of mercury is not, from obvious reasons, so well employed. There are many persons of a peculiar idiosyncrasy who appear to be susceptible of a very small quantity of mercury, and are terribly salivated by the mere administration of one dose, which is given to act as a purgative or alterative.

The symptoms belonging to excessive salivation are general and local. The former consist in

great prostration of the strength, a low irritative fever, and extreme rapidity and feebleness of the heart's action; there is also in some cases, but not in all, a marked disturbance of the nervous system. The local symptoms belong to the mouth and face. There is immense swelling of the face and eyelids, so that the features of the person cannot be recognised; the tongue protrudes from the mouth, and there is a profuse flow of saliva, of a horribly fetid smell; scarcely permitting the attendant to approach his patient. Beside these, the gums, tongue, and cheeks ulcerate and slough; the patient is not able to open his mouth, and he is hourly in danger of being suffocated. Hemorrhage sometimes takes place to a great extent, either from the nose or mouth; and, finally, if the case is to terminate fatally, gangrene of the cheeks appears, and spreads rapidly. Many instances of a fatal nature have been related, but fortunately we seldom witness such an occurrence in these days; but I have had the misfortune to witness one case of the kind since I entered upon the study of the medical profession, and although it occurred some years ago, and I have not exact notes of the case, it made so much impression upon me at the time, that I shall be able to give a pretty accurate account of it. In the year 1844, a boy, nine years of age was attacked with dropsy, after scarlet fever; calomel, in moderate doses, with diuretics and diaphoretics, was used, with some slight improvement at first; the symptoms, however, increased, and sudden effusion into the pleura took place. The gentleman who was called to the case saw the danger of speedy suffocation, unless the fluid could be absorbed; he therefore, with this view, prescribed one grain of calomel, every two hours, with great benefit; the effusion gave way rapidly, but, unfortunately, the numerous and frequently repeated doses of calomel produced intense salivation. At this time the boy was left under my charge, in consequence of the absence of his ordinary attendant from town. The symptoms increased. The whole face was enormously swollen, the flow of saliva was profuse, and the fœtor in the room was almost insupportable. There was so much inability to move the jaw that, in order to get anything into the stomach, I was obliged to use the handle of a spoon to force open the teeth; and this was accompanied with so much pain that it was quite distressing for me to do it. The mouth was blocked up with a foul viscid fluid, which it was necessary to clear away with the fingers. Ulceration of the gums and cheeks took place, and sloughing followed. There was extreme depression of the vital powers, and the suffering was intense: the poor little lad could only express it by some means, for he could not speak. He remained in this state for several days, and I thought the symptoms appeared to lessen somewhat, when, unfortunately, hemorrhage from the cheek came on twice to a large amount (I suppose from implication of the labial arteries in the sloughing process), and shortly afterwards a gangrenous spot appeared on the left cheek, and rapidly increased. The general symptoms were much aggravated, and he rapidly sank. It was the most horrible and distressing case I ever witnessed, and I hope I may never see such again. Everything that could be thought of was done: leeches and fomentations were applied to the jaws; gargles of chloride of soda; alum and other astringents were used; the constitutional powers were supported by bark, ammonia and as much nourishment as could be got down. I think he would have recovered had not the sudden hemorrhage, which was to a large amount, taken place; this appeared to me to have been the cause of the gangrene which followed, and which indicated such a disorganization of the blood and the powers of life that recovery could not be looked for. Here there was no peculiarity in the patient, but a large quantity of mercury was thrown into the system, and its effect was enhanced, no doubt, by the blood being already impoverished from the disease of the kidney, and it is rather a curious fact, that mercury appears to act with greater energy and do more

dischief in those diseases where the blood is drained of its more solid parts. In less formidable cases, even though the symptoms may have been extremely severe, recovery takes place; but the real mischief produces most serious results, and often renders the patient miserable for life. My friend Mr. Druiitt has referred me to a case which happened under his own care, and which is published in "The Provincial Journal," vol. ii., p. 428. It is so interesting a case, and so well shows the unfortunate accidents which may take place from excessive salivation, that I shall sketch it for my readers. The patient was a young married lady, whom Mr. Druiitt attended with an attack of puerperal convulsions. He prescribed, as a purgative, eight grains of calomel with some jalap; a few hours afterwards her tongue was painful and swollen; next day it increased greatly, and the face began to swell; there was frightful salivation, face and throat were enormously swollen, and the eyelids were perfectly closed by the œdema; the tongue projected from the mouth, and the membrane covering its under surface, and the inner side of the gums and cheeks, sloughed, and the saliva was so profuse that it saturated six dozen napkins in twenty-four hours. In the midst of his misery she was delivered of a child. By great care, however, she rallied, "but" (says Mr. Druiitt) "a new misfortune happened. The inside of the cheeks and gums, and the under surface of the tongue, which had sloughed, healed with a dense white cicatrix, which greatly impeded the motion of the tongue in speech and mastication, and prevented the mouth from being opened more than an inch."

This sloughing of the mucous membrane of the mouth, and the subsequent healing and cicatrization of the parts, is a very serious consequence, as it is very difficult to prevent the parts which are in contact from uniting, and thus, adhesion may take place between the membrane lining the cheek and that lining the alveoli of either jaw; or such a firm and contracted cicatrix may take place inside the cheek, that the muscles which move the jaw may become involved, and the powers of motion seriously affected; or the tongue may become adherent to the gums, or to the side of the cheeks. An instance of the latter I am obliged with by Mr. Haynes Walton, who saw the case. The patient was a female who was severely salivated for some venereal complaint; the local symptoms were of a formidable nature. There was such great protrusion of the tongue that it could not be reduced; the membrane lining its inner sides and the corresponding part of the cheek sloughed; firm adhesions took place, and after the salivation had subsided, her tongue remained protruding and united with the cheek, so that it was necessary to perform an operation, which finally succeeded in restoring the tongue to its proper situation.

Cases are frequently seen in which salivation has been carried to an unnecessary extent, and very uncomfortable, but not injurious, results have followed. The symptoms, although of somewhat the same character, do not run on to such a formidable extent. There is great swelling of the face, soreness of the mouth and throat, so that the patient is not able to swallow the blandest fluid; there is a great flow of saliva, but ulceration and sloughing do not take place as in the more severe cases; nevertheless the patient suffers extreme distress, and sometimes there is considerable prostration of strength, especially when the subject is a female; and I have noticed that women are much more easily affected by mercury, and more frequently exhibit severe cases of salivation, than men.

All these symptoms above mentioned indicate that the chief mischief is acting through the blood, and that the constituents of that fluid are greatly altered in quality. The sloughing and gangrene of the cheeks show an exceedingly altered state of the blood, which produces severe local inflammation and its results. These facts, then, I think go far to prove that this mineral acts by becoming absorbed into the blood, and changing its qualities: for how are we to account

for them? Not surely by its action on the capillaries, nor by its effect on the sympathetic system of nerves.

In the cases which I have been speaking of, nervous symptoms are not particularly noticed; but when mercury has become absorbed through the lungs and skin in large quantities, as happen in artisans working in mercury, we find poisoning by it, accompanied with well-marked nervous symptoms, constituting the disease very aptly called mercurial tremor. Any one who has seen a severe case can judge well of the effects on the nervous system. The incessant trembling of the limbs, and inability to control the muscular movements, the great agitation and depressed state of the mind, all show that the nervous system is severely implicated; and this is easily explained by the fact that all substances which are powerful and poisonous in their action produce a much more severe effect when absorbed by the lungs as vapour, than when taken into the stomach; and this effect is most marked on the nervous system. How quickly do we now see the action of ether produced, when inhaled, and how marked is its influence upon the nervous system! How much more quickly and severely does a person become intoxicated by inhaling the vapour of alcohol, than by merely taking its fluid into the stomach!

I shall now proceed to consider another injurious effect of mercury, which often proves very troublesome and even dangerous to the patient, and perplexing to the practitioner. I mean the violent purging which ensues when mercury is given in moderate doses with a view to its acting specifically on the system. It often takes place even when the mercury has been carefully given and combined with correctives, and it is most frequently noticed to take place when the gums cannot be affected. In fact, it appears as though the mineral was not able to act energetically upon the system at large, and upon the secreting apparatus of the intestines as well: for when salivation is produced, the bowels become constipated and require purgatives, and, on the other hand, when a profuse secretion is taking place from the bowels, no effect on the gums is noticed. This fact did not escape the observation of Sydenham, who says—"Non dumquam accidit, quod post unam vel alteram inunctionem. Natura illico per intestina hunc hostem expellere satagat, unde non solum dejectiones mucosae et tormina ventris, ut in his quid dysenteria laborant, eveniunt, verum etiam curatio morbi impeditur utpote qui salivationi tantummodo cedere solent." He then, after recommending some remedies, says—"Diarrhoea tandem cohibita, salivatio debito modo procedere solet, quae antea vix apparerit."

Sometimes, however, cases are seen where there may be profuse purging, at the same time that there is a specific effect produced on the system, as evidenced by the state of the gums; although, for the most part, if purging is produced early and to any great degree, there will be a great difficulty in affecting the system in a satisfactory manner. This affection of the bowels comes on sometimes quickly and severely, sometimes more gradually. But it is when it comes on very suddenly, after a larger quantity of mercury has been taken, that it proves the most troublesome and dangerous; for that it does prove dangerous, and even leads to a fatal result, I shall presently show; for I shall relate three cases which were under my own care, where a most alarming catharsis was suddenly produced, and, if not the immediate cause of death in one, at least caused a more speedy termination.

The first case was that of a woman, aged thirty-eight, whom I attended for a violent attack of puerperal convulsions, which was followed by most severe uterine inflammation. Bloodletting was employed, and I prescribed calomel, carefully combined with opium, every four hours. She took about 3ij., without any sign of the system being affected; but when she was recovering sensibly from her dangerous attack, a most violent catharsis set in and brought her again into a most alarming condition. The eyes

became sunk, the face anxious, and the pulse running on at a most rapid rate, and I was afraid I was about to destroy my patient with the remedy which I had used; but by the speedy administration of opiate emata, by the use of diffusible stimuli, and by constant watching, she rallied, and ultimately recovered, although her convalescence was long. I fortunately had the advice of my friend Dr. Fincham, of Spring-gardens, to whose attention the salvation of this woman's life was chiefly due. I must confess that at one time I was seriously alarmed for her safety.

About six months after this, Nov. 2, 1844, I was again much alarmed for the safety of my patient, through an occurrence of the same kind, and quite as severe, although the condition of the patient was not so bad as the first when it happened. It happened in a female, aged thirty, whom I attended for a severe attack of acute rheumatism accompanied with symptoms of heart disease. There was an unusual state of depression in this case, not generally observable in rheumatism; she had a great tendency to faint. Bleeding was not resorted to, but I prescribed calomel, gr. j. Dover's powder, gr. iv. every six hours; on the 3rd it was taken every four hours; on the 4th it was taken every six hours, and the Dover's powder increased to gr. v.; no affection of the mouth at all. In the night of the 5th she was suddenly seized, with most violent catharsis which was harassing her all the night, and reduced her to such an extent that delirium came on, and when I was summoned to her I found her in a very low condition, and was obliged to give ammonia and wine, with medicines to check the secretions from the bowels. By care she came round again and soon got well. There was one curious fact I noticed which although foreign to the subject, is worth mentioning. The painful affection of the joints was suddenly removed by the purging; but when this was stopped, and the system had become tranquillized, they returned with great severity again.

In the third case the sudden and severe purging was the cause of death, or at least greatly accelerated the fatal termination. It happened in a fine young unmarried woman, whom I attended for an attack of typhoid puerperal fever, Nov. 1, 1845. The collapse was great, and the uterine inflammation severe. Calomel gr. ij. P. ipec. co. gr. v., was prescribed every three hours, at nine A.M. At eight P.M. I saw her; she was evidently better, and I felt more easy about her; the mercury had not affected the mouth. Nov. 2, I called at eleven, and was sorry to see a great change in my patient; on asking about the cause, I was told that purging had suddenly set in a short time after I had left her the preceding evening, and had harassed her dreadfully all night; but they had not the sense to send for me. I found her in a dreadful condition: collapse had again come on; countenance was anxious; great restlessness; rapid and feeble pulse. The purging was restrained as soon as possible, and stimulants were given; but from this time, although she rallied somewhat, the symptoms were much aggravated; extreme depression came on, and she died in the night of the 4th.

(To be continued.)

ON SOME POINTS CONNECTED WITH DIABETES.

By M. BOUCHARDAT.

Translated for the MEDICAL TIMES by ALFRED MARKWICK, Esq., Surgeon to the Western German Dispensary, and formerly Externe to the Venerable Hospital, Paris, &c.

(Continued from p. 114.)

This case relates to a young lad aged fourteen, who had been suffering from diabetes for more than six months, and who was continually falling away, notwithstanding an enormous appetite, which he satisfied by good food, in which, however, feculents were included. His strength had

greatly decreased; and his moral depression was so great that it was found necessary to interrupt his studies.

The first time I saw this young patient, he had eaten the day before with an excellent appetite; feculents formed a portion of every meal, but to what extent was not determined. He passed in twenty-four hours 6.25 litres of very pale urine, of specific gravity 1.040 at + 15°, having to the naked eye a rotation of + 14° in a tube of 303 millimètres, and containing 104.65 grammes of glucose per litre.

This patient was immediately covered in flannel, and the diet I have previously described was rigidly followed. He took from one litre to a litre and a quarter of Bordeaux wine in the twenty-four hours. The urine, when examined eight days afterwards, contained no glucose, and the patient himself regained his strength and flesh so quickly that at the end of two months, his parents believing him cured, sent him back to school. But ordinary diet, into which bread largely enters, was prejudicial to him: the thirst began to return, and his energy diminished. He was again taken from school, and his urine brought to me. It amounted to 2.25 litres in the twenty-four hours, was of a light amber colour, and of specific gravity 1.034; the molecular rotatory power was + 11°.5, in a tube of 303 millimètres; and it contained 82 grammes of glucose per litre.

I did not see this lad afterwards, but I firmly believe that, if the regimen has been properly persevered in, he is completely restored.

In the patient whose history I am about to relate, there are several circumstances similar to those I have mentioned in the foregoing case:—1st, it is that of a young man in whom the disease became manifested while living on ordinary diet; 2ndly, the disease was very severe; all traces of it, however were promptly removed by a proper regimen; 3rdly, a return to the school diet caused the same symptoms to reappear.

This patient had passed twelve months in a school where youths are subjected to great intellectual labour. He became diabetic, but his disease was overlooked; his strength, however, diminished; his intelligence was no longer so active, and, being unable properly to undergo his examinations, he was obliged to renounce his future prospects. It was at this period that I saw him; his disease was very severe, his appetite considerable, and his thirst excessive; his mouth was remarkably dry, and his tongue presented, to a very great extent, the appearance that has been often observed in diabetes, *i. e.*, it was entirely covered with a brownish fur. He passed in the twenty-four hours about seven quarts of a very pale urine of a whey-like odour, and of specific gravity 1.036 at + 15°. When examined in a tube of 306 millimètres the deviation was + 13°.5, and it contained 106 grammes of glucose per quart. Finding that a retired life in Paris was not suited to this patient, I advised him to return home to his parents in the country. I made him thoroughly acquainted with the regimen I recommended, insisted on the use of flannel, and prescribed for him carbonate of ammonia and theriac. All this was rigidly persevered in, and in three months the change was such, having gained flesh so much, that on his return I was completely astonished.

He adhered strictly to my regimen: feculents formed but a very small part of his food, and there was no glucose in his urine. This case might pass for a complete cure; in fact, the patient gradually took to his former kind of food and regimen. But after a time his strength began to diminish; the thirst reappeared, and with it the glucose in the urine. He again turned to his native country, where he a second time became perfectly restored. Tired of an idle life, he came back to Paris, resumed his occupation, and deviated from his regimen. The symptoms again made their appearance, and on then examining his urine I found them to exercise a deviation of + 9° in a tube of 313 millimètres, and to contain 68 grammes of glucose per litre. The patient again went into the

coun., and confined himself rigidly to the regimen. Since then I have not heard of him. This case proves that in youth we may hope for a speedy cure, and that unremitting attention is necessary in order not to destroy all the good that may have been done.

The last case I have to relate in this second series refers to a patient who was very severely affected, and on whom the disease had taken so powerful a hold as to lead one to expect a fatal issue; and yet this patient succeeded by uncommon willingness, rare intelligence, and by daily care, in regaining a state of health which many persons would envy.

He has suffered from the disease, in all probability, for several years, and has at length become considerably emaciated. Formerly he was tolerably stout; but now he is literally skin and bone, and he can scarcely advance a few steps without feeling fatigued. The least labour overcomes him, and he is compelled to abandon the important matters which he directs.

Several methods of treatment having proved unsuccessful, his medical attendant had recourse to the one I have recommended in my "Annuaire." The patient derived considerable benefit from it; but owing either to its not having been strictly attended to, or to being unacquainted with my remarks, and consequently unable to apply them, his condition remained stationary and sufficiently alarming to induce him to come to Paris for my advice.

He was greatly reduced, pale, and remarkably weak; he passed on the 8th of November, 1841, in the twenty-four hours, three quarts of urine of specific gravity 1.040 at + 15°. This urine when examined in a tube of 303 millimètres, exercised a rotation of 11°.5, and contained 82.19 grammes of saccharine matter per litre. I had the common bread immediately replaced by gluten bread, and ordered him a quart to six pints of good Bordeaux wine, to wear flannel, and to take carbonate of ammonia and theriac. The urine was analysed again on the 15th of November, when the specific gravity was found to be only 1.031, and the rotation to have decreased to 3°.5; the proportion of glucose per litre was now only 31.07 grammes, and the quantity of urine voided in the twenty-four hours but a litre and a quarter. The atmosphere at this period became cold and damp; the patient increased at his meals the amount of feculents; and, under this twofold and baneful influence, the glucose progressively increased in his urine. Thus, on the 21st of November he passed a litre and a half of urine, of specific gravity 1.034, exercising a rotation of + 5°, and consequently containing 38.4 grammes of saccharine matter per litre. On November 27th, the quantity of urine remaining the same, the specific gravity rose to 1.039, the deviation to + 9°.5, which gives the proportion of 71.66 grammes of glucose per litre; on the 3rd of December the specific gravity returned to 1.040, and the deviation was + 8°, which makes 61 grammes of glucose per litre, the quantity voided being two litres. On the 14th, the density and quantity remaining the same, the deviation rose to + 8°.5, which is equal to 66.5 grammes per litre. I ought to mention that, during this period of recrudescence, the carbonate of ammonia had been replaced by bicarbonate of soda, the dose of which had been gradually increased to 30 grammes in the twenty-four hours. Carbonate of ammonia was, therefore, best adapted for this patient, and we, therefore, returned to it. From this time the quantity of urine passed in the twenty-four hours remained nearly stationary until towards the end of the treatment, being about six pints, which but little exceeds that of health; its composition, however, progressively improved, as will be seen. On the 26th of December the density was only 1.036, the rotatory power + 5°.5, and the quantity of glucose had become reduced to 41.7 grammes per litre. On the 2nd of January, 1845, the specific gravity being the same, the deviation decreased to + 5°, and the quantity of saccharine matter to 38 grammes. On the 9th the density was still the same, but the deviation had still

diminished to 4°.5, while the proportion of glucose was 35 grammes. On the 18th, no alteration had taken place in the deviation, and consequently in the quantity of glucose, yet the density became increased to 1.038; but on the 25th it descended to 1.030, and the rotation was only 2°, and the urine contained only 23.30 grammes of saccharine matter per litre. We had now arrived, for this period of winter, at the height of the improvement. A slight increase subsequently took place: thus, on the 1st of February, the density rose to 1.034, and the deviation to + 4°. On the 3rd of February we had reached a specific gravity of 1.026, and a deviation of + 6°.5, which makes 50.5 grammes of glucose per litre; still it must be stated that great lowness of spirits coincided with this slight increase in the diabetic symptoms. On the 8th the density returned to 1.032, and the deviation to + 4°; and on the 15th, the density being 1.038, the deviation became 4°.5, which corresponds to about 35 grammes of glucose per litre. Notwithstanding an unfavourable season, this patient continued to proceed towards a complete recovery. His strength, vivacity, and moral energy had gradually returned, but he had not entirely regained his flesh, although there was in this respect likewise considerable improvement. It was decided that this patient should return to the country, and engage himself as much as possible in manual labour, and particularly in gardening, and at the same time recommence his mental occupations. On the 17th of March one of his urine was sent me; the quantity was somewhat less, but the specific gravity was still 1.036, and the deviation + 5°, which is equal to about 38 grammes of glucose per litre. From this time the improvement was tolerably rapid: thus, on the 17th of April, the deviation was only + 2° and the density 1.028, the urine, consequently, containing only 15.5 grammes of saccharine matter per litre. I again analysed the urine four times up to the 2nd of September, and its composition was found to be nearly the same; it diminished but little in quantity, but the general state of the patient continued to improve. At length, on the 7th of September, the last time I examined the urine, the specific gravity was only 1.024, and no deviation could be detected with Biot's apparatus.

The preceding case, in my opinion, is a very remarkable one; it is that of a patient who was as strongly affected with diabetes as it is possible to be: the disease, moreover, was of long standing, and had produced effects which might have been considered as irreparable. But aided as I was by a man who was desirous of getting well, and who, to attain this end, was willing to sacrifice everything—a man of determined will and rare intelligence—I succeeded in effecting an unexpected restoration.

To witness now the activity, the ardour, and the good looks of this patient, one would imagine, as indeed do his relations and his most intimate friends, that he is no longer ill. In one sense, this is true; but, to preserve a good state of health, constant attention and daily care will still be for a long time necessary, and I have the firm conviction that in this M. will not be wanting.

Before concluding this case, I may state that several therapeutic remedies that were recommended, both by the celebrated physicians whom the patient consulted and by myself, were of considerable benefit. Of these I will mention, first, the preparations of iron which were in almost constant use; the wine of bark, which he took for a long time; and calcined magnesia, often prescribed as a laxative when the bowels were at all constipated. I need not allude to the carbonate of ammonia and theriac, as they constitute an essential part of my mode of treatment. The fixed alkalis, as the bicarbonate of soda, proved more injurious than useful.

THIRD SERIES.—CASES OF RECOVERY.

[Our author gives five cases of recovery in females, three of which I subjoin, and states as the result of his experience, that "diabetes is more uncommon in France in females than in

men," and that, "when there are no tubercles in the lungs, the cure is more prompt and more easy."]

Madame A., aged sixty-six, was formerly of a strong and robust habit of body, but her strength has gradually diminished, and she has lost flesh considerably. She consulted a skilful physician, who, on examining all the functions, immediately detected the relation that existed between the dry state of the skin, the excess of urine over the quantity of fluid drunk, the intense thirst, and the emaciation rapidly progressing, notwithstanding an enormous appetite and an abundance of food. Madame was sent to me: I examined the urine, of which she passed 5.50 litres in the twenty-four hours; its specific gravity was 1.011, and it exercised a molecular rotatory power of 10.50 in a tube of 308 millimètres, and contained 80 grammes of glucose per litre. I ordered her to wear flannel, and to persevere with the regimen I have already alluded to; which she did. She called on me again at the expiration of eight days; she then passed only a litre and a quarter of urine of specific gravity 1.031, producing a deviation of + 3°.5 in a tube of 303 millimètres, and containing 32.07 grammes of glucose per litre. I then prescribed boluses of carbonate of ammonia and theriac; the dose of the carbonate being gradually raised to five grammes. At the end of eight days I again analysed the urine, and its density was only 1.023. Optical examination and Frommherz's test proved that it contained no trace of glucose. Fifteen days afterwards I found it to be still absent. Madame had completely regained her strength, and she returned to the use of feculents, although in moderate quantity; and, notwithstanding that, the urine was found to contain no trace of saccharine matter when examined six months afterwards. Madame then indulged to the utmost her taste for feculent food; the consequence—the thirst returned, the urine became more abundant, and the previous symptoms reappeared; but, warned by experience, she had immediate recourse to the former treatment. I analysed the urine a few days afterwards, and found that it had no rotatory power. Since then Madame A. has regained her usual health.

Madame B. is at the head of rather a large establishment, where great activity is required. Although tolerably robust, she was taken suddenly, after suppression of the perspiration, with intense thirst, without any diminution of the appetite. The skin is dry, and the urine so abundant as to attract the attention of both the patient and the physician. It was sent to me to be analysed. It was limpid and pale; had a slight odour of whey, and a specific gravity of 1.041. The quantity in the twenty-four hours amounted to about eight quarts. Examined in a tube of 303 millimètres it had a deviation of 11°, and contained 82.19 grammes of glucose per litre: a very large proportion, considering the amount of urine passed in the twenty-four hours.

Madame B. immediately took to wearing flannel, and likewise to the regimen before described. The urine immediately diminished and became reduced to the normal standard. I examined it six days afterwards. It had then no action on polarized light; did not reduce Frommherz's test, and consequently contained no glucose. I analysed it again at the expiration of eight days, and found it still free from glucose. I have since repeatedly heard of this lady. Her health continues excellent, and she has had no relapse. She uses feculents in moderation. This case is remarkable for the rapidity and the certainty of the cure, although it must be owned the treatment was commenced at the onset of the disease.

Madame C., aged sixty, of a very robust habit, complains of general weakness, of great thirst, and a more abundant excretion of urine than natural. There is no alteration in the appetite. On the 9th of March, 1845, she passed in the twenty-four hours about three quarts of a light amber-coloured urine of specific gravity

1.041; examined in a tube of 303 millimeters, it exercised with the polarizing apparatus a deviation of $+10^\circ$, which gives 77.57 grammes of glucose per litre of urine. Madame immediately put on flannel clothing, and followed exactly the regimen I have described. She soon improved; the skin became moist, and the urine normal in quantity; still she persevered in the regimen. On the 26th of March she passed a litre and a half of specific gravity 1.025, having scarcely any action on polarized light, the deviation being barely $+1^\circ$; it contained per litre 7.5 grammes of glucose. Madame still continued to rigidly adhere to the regimen which had proved so successful; and on the 5th of May I again examined the urine. The quantity in the twenty-four hours then amounted only to two pints and a half; it was of a dark colour, had a specific gravity of 1.015, but no molecular power, and consequently was free from glucose, which was also proved by Frommherz's test. Madame therefore returned, although to a very moderate extent only, to the use of feculents, taking care, at the same time, to observe every other hygienic rule. When last examined, the urine had a specific gravity of 1.020, and was free from any rotatory power. This may be considered a perfect cure, Madame C.'s health being as good as before the diabetic attack.

M., a physician in the prime of life, and of a strong constitution, having a very extensive country practice, to the laborious duties of which he attends without fatigue. Gradually, however, his strength diminished, and he became emaciated. On examining the state of his functions, he found that he was labouring under diabetes, and he immediately came to consult me. He passed in the twenty-four hours 3.50 litres of urine, of specific gravity 1.037, containing 55 grammes of starch sugar per litre.

M. immediately had recourse to the regimen I prescribed for him, and took care to cover himself with flannel. The urine was examined at the end of two days; it had no power on polarized light, and contained no trace of starch sugar; its specific gravity was 1.030, and its colour and composition were normal. Before M. left Paris I again analysed his urine, and found that the glucose had returned in it. The following is an extract of a letter I received from M. on the 18th of January, 1841:—

"I am happy to inform you that since the 8th of October, the day on which I left Paris, I have not detected a single atom of sugar in my urine, either with the densimeter or by mixing and subsequently boiling it with one-third of milk of lime. Once, it gave me 1.030; but when boiled with the milk of lime, it became as clear as when first passed; now, it does not exceed 1.015 to 1.025, neither has it for a long time past. Sometimes when passed immediately after a meal, which is very rare, it has only the density of water, viz., 1.000. Generally speaking, however, it has a well-marked amber colour, an acid reaction, and is small in quantity (from 1.50 to 2 litres in the twenty-four hours). I have wonderfully improved in strength and flesh, and my sight, which had become so weak, is now completely restored. I feel likewise (and it is this which leads me to believe in a cure, if not already effected, at least very near at hand) that internal sensation of health, and that courage which one cannot describe, but which one experiences after having been deprived of them. Thanks then to you, Sir, who have done so much towards combating this, in the opinion of all physicians, fatal disease. Those diabetics whom you have treated, or who have been so by others on your principles, ought to feel themselves, as I do, greatly indebted to you.

"The only addition I have thought proper to make to your treatment has been to conjoin with the total abstinence from feculent food the internal administration of the preparations of iron. Loathing is soon felt when one is deprived of bread; and those preparations, if they have only the advantage of promoting an appetite, appear to me greatly to be recommended. You have doubtless, like myself, tried these remedies,

and must have found benefit from their employment.

"In concluding my remarks on the treatment you have prescribed for me, and which has proved so useful in my case, I may state that I intend visiting you as soon as I can, for the purpose of getting you to again analyse my urine with M. Biol's apparatus, by which alone a correct estimate of this fluid can be obtained."

This patient visited me on two occasions, and I always found the urine to be free from starch sugar; notwithstanding, however, it appears, from the examinations he himself continually made, that on one or two occasions, after having taken a rather larger quantity of feculents, glucose appeared in his urine; but it immediately disappeared on again returning to the regimen.

Although for a day or two a few traces of sugar could be detected in the urine, still I consider this a case of complete cure; in fact, if we were to examine our urine daily, with this view, is it not possible that we may occasionally find in it traces of glucose? Our experiments on the digestion of feculent and saccharine matters warrant this supposition; it is therefore a slight and simple aberration of a natural function.

Since M. came under my care he has himself had three others, in which he has tried this mode of treatment; but, like myself, he has obtained different results according to the difference of fortune and intelligence of the patients.

Prout, who is a very great authority in diabetes, says that in his great experience he has only once found the urine of these patients return to its normal composition. In the sixteen cases reported by M. Bouchardat in this series, it has not been a transitory change, but a lasting return to its healthy composition; they are cures from which there has been no relapse for several years.

Langham-place.

A NEW MODE OF TREATING UTERINE HEMORRHAGE.

By T. R. TORRICK, M.D.

(Continued from p. 116.)

CASE III.—Mrs. M., aged forty-four years, an exceedingly delicate female, and of a strumous habit, had given birth to several children, her last accouchement being followed by great exhaustion consequent upon flooding; more than once her life had been de-paired of. Not being her usual medical attendant, I requested to be sent for in good time, her mother having informed me "she had very quick times." The period having arrived, her accouchement took place—natural; there being nothing untoward until the removal of the placenta, when truly it may be said the blood flowed forth in a torrent; being now prepared with a suitable apparatus, I at once injected into the uterus three ounces of whisky diluted with one-third water, when contraction instantly followed, the hemorrhage being completely arrested. It is somewhat singular, in this case, that the patient did not suffer from afterpains, which had been a source of the greatest distress in her former accouchements; her statement to me was, that "she had never recovered so well in all her former labours."

CASE IV.—Mrs. P., aged forty-two, a female of spare, delicate habit, from the neighbourhood of Wolsingham, had come to Sunderland for the improvement of her health: utero-gestation being, as she supposed, about three months advanced. A few days after her arrival she was seized with violent pain in the loins, attended with "bearing down," which continuing, terminated in the expulsion of the fetus, accompanied by severe flooding. A messenger was immediately despatched for me; but her residence being at least half a mile from my own, there was consequently considerable delay. On my arrival I found her apparently *in articulo mortis*, her friends looking over her for dead; that "I had arrived too late to be of any service, and that the loss she had sustained was dreadful." It was true, there was no pulsation at the wrists, neither

did she appear to breathe, and when the fluids were poured into the mouth they flowed by its sides, being unable to swallow, such was the state of prostration. On examining the uterus, *per vaginam*, I at once found the cavities throughout filled with coagula. I immediately introduced the uterine tube of the apparatus, and washed away the whole of the coagula. The mouth of the uterus was exceedingly loose and flabby; three ounces of gin were then injected, when feeble contraction took place—the hemorrhage ceased. In the interim the region of the heart was rubbed with stimulants, and which were also administered by the mouth, being now restored to consciousness, so as to be able to swallow; notwithstanding the patient continued in a very feeble state for some time, the hemorrhage was arrested completely, and she ultimately recovered.

CASE V.—This case, at the period in which it came under his care, was reported to me by my much-esteemed friend, Wm. Reid Clancey, consulting physician to the Sunderland and Bishopwearmouth Infirmary, who is an accoucheur by diploma from the University of Edinburgh; and, though he has ever since practised as what is called a *pure physician*, his valuable advice, during a very lengthened period has been held in high estimation in obstetric cases, in the sphere of his extensive practice. To this gentleman I had made known my views and experience upon the point in question, some time previous to his having been called to the case, and taking sole management of it; and, according to the information which I had furnished him, the time had now become opportune when he was enabled to suggest their adoption. Mrs. B., a plethoric female, aged forty, was suddenly seized with violent pain in the loins, accompanied with "bearing-down efforts;" at this period she was said to be in the third month of utero-gestation; her usual medical attendant was sent for, and on his arrival discovered the ovum had been thrown off, and the hemorrhage abated. Two or three days had not elapsed when a profuse hemorrhage ensued. Dr. Clancey was immediately sent for by the family, and on his arrival, found, on inquiry, that the placental portion had not been thrown off. The medical attendant was instantly summoned, when the doctor ordered the injection of spirits of wine, diluted, into the uterus. Shortly after the injection (which was performed by the medical attendant) the placenta was expelled without pain, and the hemorrhage ceased, though the patient's strength was considerably prostrated. This female, a few months afterwards, became *en-cante*, which affords a direct proof that the normal functions of the uterus had not suffered detriment from the timely use of the alcoholic mixture.

Kirkby Stephen, March 30.

PROGRESS OF MEDICAL SCIENCE.

France.

ACADEMY OF MEDICINE.

Meeting of April 13; M. BEGIN in the Chair.

YELLOW FEVER.

An official letter from the Minister of Commerce was read, containing a communication from the French Consul at New Orleans. For the last few years cases of yellow fever had become less and less frequent, and since the beginning of this year not a single case had been observed—a result which his Majesty's vice-consul was inclined to refer to the recent drainage of considerable marshes in the vicinity of the town. It was probable that, in consequence of this sanitary improvement, the ships homeward bound would all receive this year clean bills of health.

M. F. Dubois remembered that some years since similar hopes had been entertained at Vera Cruz, but were not realized. Baron de Humboldt

had noticed in these latitudes periods of eight and ten years, during which no cases of yellow fever were observed, and at the end of that time the disease had had reappeared with all its former malignity.

SATURNINE INTOXICATION.

M. Martin Solon read a report on a communication from Dr. Millon, referring to the diagnosis between poisoning by lead and by copper, and to their treatment by sulphurous preparations.

M. Orfila remarked, that the paper asserted that the viscera of persons affected with colica pictorum contained lead. The learned professor did not think that this assertion was supported by sufficient chemical proof. Two cases might occur: in one, saturnine preparations had been taken into the stomach, and symptoms were produced which had but little analogy with those of persons labouring under the painter's colic. The phenomena observed were those of irritating poisons. In this case the metal was taken up in the stomach by the absorbents; and when the liver was merely boiled in water, this fluid became loaded with the poison without affecting what may be called the normal or natural lead. When, on the contrary, chemists have endeavoured to detect the poison in the organs of persons affected with colica pictorum, the viscera had been carbonized previously to any analytical research, and in these instances the lead discovered was that which he would call normal, i. e., naturally existing in the system. Mere maceration in boiling water of the liver of persons who had died of painter's colic would in no instance permit the extraction of the poison.

M. Martin Solon stated that the urine of patients affected with colica pictorum contained lead—a circumstance which showed the importance of acting on the kidneys, in order to facilitate the expulsion of the poison from the system.

M. Guibourt was of opinion that the lead and copper found in the viscera of healthy subjects arose exclusively from the vessels in which the food had been prepared in the countries in which the use of iron vases was general. M. Guibourt was convinced that neither copper nor lead could be detected in the viscera by the strictest analysis.

M. Orfila asserted this to be an erroneous opinion: the learned dean had always found lead and copper in the organs of man, whenever he had sought for it; the presence of these metals in the body was certainly not the result of accident. From M. Sarzeau's statistical researches, it appeared that in France only, during the course of one year, 2650 kilogrammes of copper were absorbed with the food.

Meeting adjourned at five o'clock.

PARISIAN MEDICAL SOCIETY.

Meeting of April 7; Dr. SHRIMPTON in the Chair.
HALLUCINATION RELIEVED BY ETHERAL INHALATION.

The following interesting case was communicated by Dr. Trayer:—

In the year 1821, a young lady was deprived, by a short and fatal illness, of a highly-valued and much-beloved friend. Under this severe affliction she imposed upon her feelings a degree of restraint, the evil consequences of which showed themselves eight days after, by the sudden manifestation of a most distressing hallucination, which has persisted ever since that period: it consisted of the vivid and constant perception of the countenance of her departed friend close to, almost in contact with, the eyes, and of dimensions so much greater than natural as to be monstrous, with a painful expression, and surrounded by other accompanying horrors. Several months passed without any alteration occurring in the original phenomenon: change of scene was of no avail; and, at the expiration of one year, symptoms of a violent spasmodic nature made their appearance. The hours of day were now passed in a species of trance, while at night the patient awoke not only to consciousness but activity of mind, the vision

being always present during her waking hours. This condition lasted for about six months, when she recovered from it, but not to health, being during nine years more a prey to various forms of this ever-changing malady. The original affection of the sight was, however, an unvarying symptom—the connecting link that chained all these sufferings into one disease. About this period the hallucination began to disappear for a short time during the summer months, but never remained long away, always disappearing suddenly, and as suddenly returning. Shortly after, the vision ceased with regularity, from June to December. During sickness it seemed to produce a momentary species of delirium of a very curious nature. It ran on the same melancholy topic which originated her disease, but was of a quiet, mild character, ceased by a powerful exercise of volition, and never incapacitated her from arranging with precision the most minute domestic concerns. At the end of Dec., 1846, the spectre returned at its usual date, and with rather increased intensity, becoming a serious impediment in walking, reading, &c. Dr. Trayer was called into the patient during the month of Jan., 1847, when he recommended a tonic, and at the same time antispasmodic line of treatment, together with bodily exercise, &c. The patient declined for the present taking any medicines, and shortly afterwards Dr. Trayer was induced to hope that the unconsciousness produced by the inhalation of ether might exercise a favourable influence upon this singular and painful disease. These hopes were realized. Ether was inhaled on five successive occasions, and at each the vision gradually diminished in size and distinctness, finally departing altogether more than six weeks before the usual period of its dispartition.

EXTRACTS FROM PERIODICALS.

DIAGNOSIS OF VENOUS ANEURISM.—In several forms of spontaneous aneurism, or of false circumscribed aneurism, the tumour is the seat of a certain tremor which might lead to an erroneous belief in the existence of aneurismal varix. In order to render more positive the diagnosis of this condition, in which a vein and an artery are placed in communication with each other, M. Nelaton assigns the following three signs to venous aneurism, and considers them as pathognomonic of the disease:—1. A double soufflé, corresponding to ventricular contraction, and to arterial systole. 2. A continuous tremor. 3. The existence of this tremor in a considerable extent of the course of the vein.—*Gaz. des Hôpitaux*.

PARTIAL ALBINISM.—This cutaneous disorder, which M. Cazenave calls "vitiligo," consists in a limited discoloration of the skin and of the hairs growing from the affected part. It has often been confounded with "porrigio decalvans," and is probably of the same nature as the white leprosy, so common during the middle ages. The disease is a most obstinate one: in a recent case observed at Hôpital St. Louis, the treatment consisted in the daily exhibition of one twelfth of a grain of arsenious acid; a very unimportant amendment has been obtained.—*Ibid*.

THE URINE DURING PREGNANCY.—The great frequency of the occurrence of a deposit in the urine of pregnant women is now very generally admitted, and has given to that deposit the value of a diagnostic sign of some precision. The nature of that deposit is still, however, unknown. M. Nauched, who of late years brought the subject before the profession, was of opinion that it was constituted by the cascum formed in the breast during gestation. The recent researches of organic chemistry demonstrate the fallacy of this notion. M. Regnault, having observed the urine in a great number of cases of pregnancy, does not hesitate to assert that the cloud observed in the secretion, when allowed to stand for thirty-six or forty hours, is due to the decomposition of an amount of azotized matter secreted in excess by the kidneys during gestation. This matter would act as a ferment in the urine, and hasten the progress of the following reactions, to which the opacity of the urine should, according to Dr.

Regnault, be attributed: gradual decomposition of urea, formation of carbonate of ammonia, reaction between the latter and the phosphate of lime existing in the fluid, and deposition of carbonate of lime. At the same time the urine loses its acidity; crystals of phosphate of magnesia and ammonia may be seen, and also an immense number of microscopic animalcules, and in such abundance that, examined with an enlargement of 600 diameters, the white layer seems to consist only of the assemblage of vibria and phosphatic crystals. The deposit observed in the urine of pregnant women is not therefore due to the spontaneous coagulation of a substance having primitively in the urine a distinct existence. It is due to the gradual decomposition of the fluid, and does not take place when the urine is protected from contact with air, and is placed, for instance, in an atmosphere of hydrogen.—*Revue Medico-Chirurgicale*.

FRACTURE OF ONE OF THE CONDYLES OF THE FEMUR.—M. Malgaigne endeavours, in a short and interesting memoir, to elucidate the history and diagnostic signs of this fracture, of which no correct description has been hitherto given. The principal signs upon which M. Malgaigne chiefly insists are the transversal enlargement of the anterior aspect of the knee due to the separation of the condyles in front only; and the remarkable deviation of the leg—the tibia following the fractured condyle in its displacement. In the fracture of the external condyle, therefore, the knee protrudes inwardly, and the outer aspect of the limb presents an obtuse angle; the reverse is the case when the inner condyle is broken. An obscure crepitus may usually be felt on pressing the patella; but the great pain which this determines, and the often very considerable effusion in the joint which follows the injury, should deter the surgeon from any very rigorous search for crepitation. Sir Astley Cooper recommended the limb to be kept extended, and a roller to be applied around the knee, over a piece of pasteboard. Sir Astley Cooper's object in recommending the leg to be placed in extension was to preserve the condyles on the same line—an intention which, according to M. Malgaigne, that position does not carry out. He prefers slight flexure of the extremity, and the application of one splint on one or the other side, according to the deviation of the leg: if it be thrown into exaggerated adduction, for instance, as in fracture of the internal condyle, the splint should be placed on the inner side, in order that a handkerchief or a bandage may destroy the displacement, by drawing the knee towards the splint.—*Ibid*.

TREATMENT OF CORYZA.—M. Deschamps, pharmacist of the Hospital of Charenton, asserts that coryza may be arrested in its incipient stage by injections, repeated twice or three times at two hours' interval, of a fluid containing two grains of extract of opium to two-thirds of an ounce of distilled water.—*Repertoire de Pharmacie*.

GUN-COTTON is used in the hospitals of Turin for the purpose of applying clipping-glasses; the deflagration of the cotton creates a sudden vacuum in the glass, and does not burn the skin.—*Giornale dell' Accademia R. di Torino*.

D. Mc'ARTHY, D.M.P.

CONFLICT BETWEEN MEDICINE AND SURGERY.—A Government regulation, battling against quackery in every form, has been well received by the bulk of the intelligence of the country, which is accustomed to have their lives and limbs protected *ex officio*. It is to the effect that the drugs and preparations for homoeopathic cases, can only be procured from the regular (licensed) apothecaries in their state and concentration enacted by the Pharmacopœia. These the homoeopathist may dilute and use as he thinks fit, but has to state on the prescription the degree of dilution, dose, &c.—a very praiseworthy precaution indeed. The Faculty of Medicine (the only branch to which a little action is allowed in Austria) are busily engaged in the reorganization of their old (!) statutes. They deprecate the interference of surgeons in internal maladies; while

the latter petition Government for being authorized to act in this capacity—a subject to be treated by us on another occasion. The medical statistics of Austria in 1846 are as follows:—Doctors of medicine, 6395; surgeons, 3985; apothecaries, 2784; which does not include those employed in the military medical service.

TO CORRESPONDENTS.

THE MEDICAL TIMES may be procured by an order on any Newsmen or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carstrac, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-yearly Subscription, 13s.; Quarterly, 6s. 6d.

A HANDSOME PORTFOLIO for holding the "MEDICAL TIMES"—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 5s. An allowance is made to the trade.

A Navy Surgeon will much oblige us by furnishing us with all the data on the subject of retiring pensions in his possession. We have already considerable information on the subject, and intend to consider it in all its bearings, with, we hope, some practical influence on the Government authorities.

Mr. Francis C. Burges.—The six lectures by Dr. Knox have not yet been published, but will be shortly.

Mr. Wm. Smith is thanked for his offer, which is declined.

C. H., Hampstead-road.—The practice you refer to is alike destructive to health and happiness. Carry out your resolutions; and, if necessary, consult some medical gentleman in the neighbourhood.

C. W. A.—The impromptu would have been better if a little more consideration had been exercised. We are compelled to decline the communication.

M.D.—No.

A Correspondent informs us that Professor Flourens has made experiments with ether of different kinds on animals; and that ether prepared from chloric acid acts more energetically than the sulphuric, while "its action ceases also in the same ratio."

A Bartholomew Student complains that the examinations at the end of the session, with a view to award prizes, &c., to the most diligent students, conducted by written questions, and in the library, were this year held in the hall of the College; and the time limited, to the manifest disadvantage of those who could not move their fingers or tongues with sufficient velocity.

F. A. S.—No.

Spectator Medicorum says that "he has been amused, but not edified, by reading Dr. Golding Bird's ideas on the subject of the title of "Dr." Our correspondent thinks "we have too many baby doctors turned out of Edinburgh, St. Andrew's, Aberdeen, and Glasgow, every year."

"Tower Hamlets" has forwarded us the copy of a circular, issued by an individual in St. John-street, Clerkenwell, asking for money to defend the criminal proceedings instituted against him for practising without a license, which circular exemplifies the fears of the author.

A. B. C. (Edinburgh) informs us, that there has been a clinical puff in a local newspaper, in reference to a certain doctor who performed the operation for squinting on a child under the influence of ether; when the notable discovery was made, that the nerve of the eye retained its sensibility longer than any other part of the body.

Dr. Torbeck's communication has been received. An Old Subscriber.—Yes.

T. O. W.—Of course.

"Cornuo" has made known the circumstance that his groom "pruned his dog's ears and ampu-

tated his tail under the influence of ether; and that the tail retained its sensibility (waggled of course) about two or three minutes longer than other parts of the body."

Not Perfect.—A little rest would be necessary after the operation mentioned. Consult your surgeon.

J. S.—If without a warrant, no; if with a warrant, yes.

Mr. Sharp has our best thanks.

Mr. Close will see that his communication has been duly regarded.

Philos has been received.

Mr. Thompson's paper is under consideration.

Käf.—We are much obliged by our friend's outline, which is very excellent. The congratulations are acknowledged with thanks.

Mr. Churchill's note had its wish anticipated.

We have received communications and letters from Dr. Wright, Birmingham; Mr. Hilles; Mr. Close, Manchester; Dr. Hilles, Norwich; Mr. Smith, Crawley; Mr. Buller, Ipswich; Mr. Lambert, Farsley; Dr. Nichol, Crask; Mr. McChayne, Edinburgh; Mr. Langlois; Mr. Hopwood, Chipping Norton; Mr. Snowden, Ramsgate; Mr. West, Camelford; Mr. Beck, Sauchibridge; Mr. Ros, Eccles; Mr. Croston, Manchester; Mr. Ellis, Walsham-le-Willows; Mr. Lambert, Bath; Mr. M'Bride, Gelford; Mr. Ball, Burslem; Dr. Grey, Liverpool; Mr. Brady, Dunfermly; Dr. Coghlan, Wexford; Mr. Baxall, Harsham; Mr. Couch, Penzance; Mr. Eggher, Pershore; Mr. Glaisher, Blackheath; a Constant Reader, Edinburgh; Mr. Kay, Plymouth; Dr. Tolbock, Kirkby-Stephen; Mr. Churchill, Pinlco.

Our correspondent at Ramsgate should order Dr. Ayres's Lectures on Agricultural Chemistry in the Pharmaceutical Times.

We shall endeavour to find room for the communication of the Medical-Chirurgical Society in our next.

The letter of Z. to the Army Surgeons shall have early attention.

THE MEDICAL TIMES' PRIZES FOR THE BEST REPORTS OF MEDICAL AND SURGICAL CASES.

The results of our last Prizes have been so far encouraging that we propose for Professional Competition, for the year 1847, the following Prizes:—

Twenty-five Guineas for the twelve best reports of original cases in hospital or dispensary practice.

Ten Guineas for the twelve reports of original cases, as above, second in merit.

Five Guineas for twelve reports of original cases, as above, third in merit.

In offering these prizes we repeat that our aim in this, as in other matters, is to promote the SCIENCE of our Profession. The groundwork of the best part of our practical science and of most of our subsequent Professional worth is laid down in our studentship; and the great and the only true teacher of the student must ever be—hospital practice. Lectures and books have their uses; but it is by the bed which holds a human being, with the joy of health or the pain of disease, the chance of life or the peril of death, depending on the aids of science, that we acquire our true knowledge. There is there for the student no listless ear, no dull eye of the lecture-room; it is not the memory alone that is appealed to, or some abstract love of a pedantic and inapplicable lore. Every power of his mind is engaged; he is forced by the sympathies of his nature to hear and see, to observe, to reason, to prognosticate; to be EXPERIENCED; each patient's case is a volume of medical science in its most practical aspect, forced on his acquaintance for life!

The authors must be students who shall not have received any medical diplomas or licences.

Six of the cases are to be medical, and six surgical.

The cases must have occurred during the year; and the names of the gentlemen under whose treatment they may have principally come must be distinctly mentioned.

Three arbitrators will be appointed—one surgeon, one physician, and one general practitioner—whose names will be duly announced. The decision will be on the 1st of July.

The Prize Reports will be published in succession in the "Medical Times," with the names of their authors.

They are to be sent to the Editor of the "Medical Times" on or before May 1, 1847, accompanied by a certificate from a surgeon or physician to a hospital, declaring that the writer is *bona fide* a medical student. A motto or device must be inscribed on each report, to identify the author, whose name, with a duplicate of the motto or device, must be mentioned in a private note, which will be opened when the award shall have been made.

THE MEDICAL TIMES.

SATURDAY, APRIL 24, 1847.

HOW STANDS MEDICAL REFORM?

It is an arduous, perhaps a disconsolate, task to work up a great movement in antagonism to the apathy and indifference of the public. The stone of Sisyphus is a universally-accepted illustration of the axiom. We are, at any time, in danger of a recoil, and the danger is greater in proportion to the elevation we have attained. Nevertheless, all labour partakes more or less of this character: even a labour of love is a warfare against difficulty; and the difficulty, in ardent and enterprising minds, only serves to increase their love.

The National Institute are embarked in such an undertaking; they are no doubt surrounded with embarrassments, the object itself being as bold and difficult of attainment as any which the moral daring of man, in consideration of its resources, has selected for its accomplishment. We believe this to be the case in reference to the end which this body seeks to compass; what are the means that are employed to bring round the result?

Every practical man will ask this question. We may admire the chivalry of engaging in a perilous design, we may esteem the generosity that dictates heavy personal and pecuniary sacrifices, we may applaud an unwearied perseverance in labour; but, after all, we covet one thing—power of practical development, that old English habit of making deeds the exponent of our labours, of realizing by the hand what the head finds for it to do. In the silence of fact is the most eloquent of arguments.

We might almost say that, in holding their *conversazione*, the National Institute have commenced a new career. They have abandoned the system of all agitating bodies—that of waiting upon Providence, and have apparently resolved to wait only upon their own energies and resources. "The gods help those who help themselves" is henceforward to be the motto of the Institute; and we are glad of it, as it conveys to the popular mind an intimation of that unchangeable resolution which must increase the confidence of their supporters, and eventually accomplish their great enterprise. The *conversazione* is then the first fact of the new era; and is, in itself, the most interesting mode of evidencing to their brethren the advantages of a general incorporation. The general practitioners have shown what they are able to do, even under the ban of corporations and the indifference of the Government; and we can only guess at the useful results that they might work out under a favourable or even a just system of legislation. Perhaps the Council of the College of Surgeons are unable to see the potency and effects of this reunion: they are burrowing blindly, like moles, in their own corruption; they are so unaccustomed to the light, that a mere glimmer shuts up their eyes; if they would see, they cannot; physical defects and long-accustomed habits have rendered them incapable of judging correctly of the sphere they inhabit. It is unfortunate for them, but perhaps advantageous to the profession at large.

The satisfaction which the recent meeting at Hanover-square gave to the members of the Institute cannot fail to react favourably upon

public opinion. The members who attended are so many missionaries of good tidings to their brethren in distant parts; and, unless the profession are totally indifferent to their own welfare and the general good, they must be roused to a renewed and warm support of the Council in carrying out further arrangements. The profession owe as much to the Council as the Council owe to the profession; and as we ventured, some time since, to remind the Council, as an elected body, of its responsibility to its constituents—a remonstrance that has been promptly attended to—so we now repeat that the Council, however anxious to promote the interests of their constituency, can do nothing without their liberal assistance. Without such assistance, confidence, and good will, they will be paralysed. We expect no miracles in these days. The man sick of the palsy cannot stretch out his hand on a mere command: the strength must be supplied, or the sinews are motionless. In the midst of the fight he is utterly impotent. The sinews of war are money. Of this, enough.

Other facts are yet to be realized by the Institute: a museum, a library, a common hall, &c.; and we hope to see them all in their turn. We cannot but think that the present decided step of the Institute is one of peculiar significance in the complex situation in which we find medical interests now involved. In sequence to the *conversations*, they have advertised their intention to summon a public meeting so soon as that long-promised measure, the Medical Registration Bill, shall have been introduced to Parliament and printed. We have only one fear—a grave one—on this matter: it is, that if the Council defer their general meeting until the Medical Registration Bill be a reasonable contingency, another public meeting will never be held. This is a very serious matter for the interests of the profession; it may be very adroit for the Council thus to defer a meeting with their constituents *ad infinitum*, but really we think the profession should immediately abrogate the plea.

There is something extremely amusing in the transformations this measure has at different times assumed. We remember, in our boyhood's days, seeing peripatetic jugglers performing sundry tricks of legerdemain with painted paper—it was now a fan, now a slipper, and now a fool's cap; we think the last the most suitable form which our political mountebank can give to his bill. It is scarcely worth while to refer more seriously to this scheme, as we feel quite satisfied, for a multitude of reasons, that it will never occupy the serious attention of the Legislature.

The Council of the National Institute must, therefore, continue to pursue an independent course. They have chalked out for themselves a plan from which no transitory considerations—perhaps designedly placed in their way with the intention of frustrating their exertions—should induce them to depart. The Council of the College of Surgeons may entertain new schemes, in the hope still more deeply to submerge their members, and to fasten more firmly the chains that now bind the various members of their profession in their respective grades: no plan of theirs can ever succeed while the National Institute does its duty. They are the watchdogs of the citadel, and it is a part of their duty to give the alarm when any new attempts are made in any quarter to fetter down the full and independent spirit of their brethren.

There can be no question that medical politics will ere long assume a different character and bearing from any of its preceding phases. Powers, hitherto inoperative and despised, are now assuming an imperative and overwhelming influence. An act of Parliament, hitherto esteemed rather of technical than real value, has acquired a new force, and threatens insecurity to one half of the existing practitioners of medicine in this country. The success of the prosecution at Bolton has utterly changed the relations of the differently-qualified members of the profession; and, while those gentlemen who have simply the diploma of the Royal College of Surgeons are at any hour liable by a summary process to a prosecution and imprisonment for practising as apothecaries, it is manifest that the question of Medical Reform cannot stand still; that it is, in short, the all-commanding interest of the members of the College to push forward the consideration of a general measure.

Are these not powerful reasons for supporting such a body as the National Institute? The members of the College should enrol themselves at once, and assist the labours of the Council. There must be but one voice to the Government on the part of the general practitioners. Emancipation in the College of Surgeons is now of less importance than ever; it is their position, their character, their bread, that they must now defend. A jealous rival, a low informer, an aggrieved patient, can, at any time, ruin a surgeon in general practice. This is too serious—too perilous a state of things to continue; and we only trust that, under this strong pressure, the profession will at last become unanimous, and require, as one man, a complete and comprehensive measure of reform, putting all the general practitioners upon a perfect equality, in rank, privileges, and immunities.

THE CRONIN CASE, AS LOOKED AT BY THE PUBLIC AND THE PROFESSION.

The philosophy of medicine, as a profession, is a something which, however well understood by medical men, is not exactly comprehended by the public, or, at least, not in the same way as by us. The people, to do them justice, resemble children in one respect: they look at actions for their conclusions, rather than words, however frequently repeated. We have been in the habit of speaking of ours as one of the most learned, liberal, and benevolent of the professions, and, doubtless, with more real than apparent truth; but the fact is, we have been unable to make the public believe us. There are numbers who will think that we push our benevolence in the face of the world to attract its applause; that we are more anxious to enjoy the reputation of wisdom than to possess the quality; and that, while we would appear busy in uprooting the foundations of error, we would erect in their place a towering colossus of pride, which we would have the world adore. In a word, and to change the figure, we are put down as old-fashioned Jacobites, satisfied with things as they now exist, utterly opposed to any innovation, and yet such Ishmaelites in constitution as to be engaged in an everlasting warfare with each other.

These remarks have some bearing on an article which appeared in the last week's number of a very widely circulated journal, and which, recently at least, exhibits a very considerable display of talent in the editorial department. The

writer goes to work upon "Doctors and their Differences" with a resolution about which there can be no mistake. Physicians he takes at once by the ears, or, rather, by that prominent organ in front, which he stoutly pulls. The poor coroner for Middlesex he makes bite the dust in a very unbecoming manner—speaking of him as one who "embraces in his own person the somewhat piebald and incongruous characters of a tribune of the people, a judge, a political partisan, a coroner, and the editor and proprietor of a medical journal called the *Lancet*." "A rival professional periodical," he goes on to say, "has ventured to point out the incongruity, and the tendency which such diverse vocations has to turn the stream of justice into a puddle. Mr. Wakley has prosecuted it for libel, and the court has very significantly intimated to the learned coroner for Middlesex, that he does not come before it with clean hands, and that the *Medical Times* 'served him right.'"

Without advertising further to the misdeeds of the individual—which we are not responsible for—let us ask, do we merit such chastisement inflicted upon us, as a profession, by that powerful instrument—the Press? Dr. Cronin was denounced and condemned by the coroner so indiscriminately, and in advance, that large numbers at once manifest their sympathy, and stand forth in his defence. The Giessen physician has been expurgated by Wakley's censures; and hence the Press—at least a great portion of it—has stood up to shield the man who has been charged by the profession with an insult to science, and a disregard of prudence to such an extent, indeed, as to produce the most lamentable results, and public censure is averted from him by a counter-charge against the whole body of medical practitioners. We may learn some very important truths, even from the lips of those who censure us.

Miss Collyer is dead—Mr. or Dr. Cronin is acquitted—Mr. Corfield still attends to his shop, and Mr. Jacob Bell yet patronizes and illuminates the Pharmaceutical Society. With the exception of an assassination and a lesson, everybody and everything are in the old position! What is that lesson? This: that the druggists, as a body, are not exactly in the possession of that amount of knowledge which persons ought to have who dispense medicines of the most energetic description.

The public entertain the notion, at least the poorer part of it, that those who sell medicines are acquainted with their properties. The idea has been diligently encouraged by those who are interested in the matter; hence, there is scarcely a physic-shop which has not its matchless anti-bilious pills, irresistible corn-plasters, and gout-destroying mixtures. The battle between physic and disease, carried on under the eye of the venders of drugs and chemicals, is, according to the testimony of many of them, one which must terminate in a decisive victory under the combined forces of boluses, tonics, and cathartics. Were it not for the "counter practice," nine-tenths of the trade must shut up shop: for the number is but small who would make more than a few shillings per day by the sale of drugs which their customers might require.
